ieee8021MstpCistTable OBJECT-TYPE
    SYNTAX      SEQUENCE OF Ieee8021MstpCistEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
        "The Common and Internal Spanning Tree (CIST) Table. Each row in
         the table represents information regarding a Bridge's Bridge
         Protocol Entity for the CIST.

         Note that entries will exist in this table only for Bridge
         components for which the corresponding instance of
         ieee8021SpanningTreeVersion (from the IEEE8021-SPANNING-TREE-MIB)
         has a value of mstp(3).

         This table contains objects corresponding to the following items
         from 12.8.1.1 and 12.8.1.3.  Some of those items are provided
         in the IEEE8021-SPANNING-TREE-MIB as noted below.

         From 12.8.1.1:
             Items a), c), o), p), and q) are defined in this table
             The remaining items are covered in the
             IEEE8021-SPANNING-TREE-MIB:
                 b) ieee8021SpanningTreeTimeSinceTopologyChange
                 c) ieee8021SpanningTreeTopChanges
                 e) ieee8021SpanningTreeDesignatedRoot
                 f) ieee8021SpanningTreeRootCost
                 g) ieee8021SpanningTreeRootPort
                 h) ieee8021SpanningTreeMaxAge
                 i) ieee8021SpanningTreeForwardDelay
                 j) ieee8021SpanningTreeBridgeMaxAge
                 k) ieee8021SpanningTreeBridgeHelloTime
                 l) ieee8021SpanningTreeBridgeForwardDelay
                 m) ieee8021SpanningTreeHoldTime
                 n) ieee8021SpanningTreeVersion
         From 12.8.1.3:
             Item g) is defined in this table
             The remaining items are covered in the
```

ieee8021MstpCistPortTable OBJECT-TYPE
    SYNTAX      SEQUENCE OF Ieee8021MstpCistPortEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
        "The CIST Port Table. Each row in the Table represents information
         regarding a specific Port within the Bridge's Bridge Protocol
         Entity, for the CIST.

         The values of all writable objects in this table MUST be
         retained across reinitializations of the management system.

         Note that entries will exist in this table only for Bridge
         components for which the corresponding instance of
         ieee8021SpanningTreeVersion (from the IEEE8021-SPANNING-TREE-MIB)
         has a value of mstp(3).

         This table contains objects corresponding to the following items
         from 12.8.2.1, 12.8.2.3, and 12.8.2.5.  Some of those items are
         provided in the IEEE8021-SPANNING-TREE-MIB as noted below.

         From 12.8.2.1:
             Items a), d), e), and i) through w) are defined in this table
             The remaining items are covered in the
             IEEE8021-SPANNING-TREE-MIB:
                 b) ieee8021SpanningTreePortState
                 c) ieee8021SpanningTreePortPriority
                 d) ieee8021SpanningTreePortPathCost
                 f) ieee8021SpanningTreePortDesignatedCost
                 g) ieee8021SpanningTreePortDesignatedBridge
                 h) ieee8021SpanningTreePortDesignatedPort
         From 12.8.2.3:
             Items a), b), and d) through h) are defined in this table
                 (item a is the index)
             The remaining items are covered in the
             IEEE8021-SPANNING-TREE-MIB:
                 b) ieee8021SpanningTreePortPathCost,
```

```
                c) ieee8021SpanningTreePortPriority
            From 12.8.2.5:
                All items are defined in this table
            Also from 12.8.2.1:
                Items u), v), w), and x) are defined in this table
            Also from 12.8.2.3:
                Items i), j), k), and l) are defined in this table"

17.7.7 Definitions for the CFM MIB modules

There are two modules for CFM as a result of the reindexing required with the addition of PBB (see 17.3.2). Since the IEEE8021-CFM-MIB module contains deprecated tables replaced by reindexed tables in IEEE8021-CFM-V2 MIB module, both modules are needed for CFM implementations.

17.7.7.1 Definitions for the IEEE8021-CFM-MIB module

Dot1agCfmMaintDomainNameType ::= TEXTUAL-CONVENTION
    STATUS      current
    DESCRIPTION
       "A value that represents a type (and thereby the format)
        of a Dot1agCfmMaintDomainName.  The value can be one of
        the following:

        ieeeReserved(0)   Reserved for definition by IEEE 802.1
                          recommend to not use zero unless
                          absolutely needed.
        none(1)           No format specified, usually because
                          there is not (yet) a Maintenance
                          Domain Name. In this case, a zero
                          length OCTET STRING for the Domain
                          Name field is acceptable.
        dnsLikeName(2)    Domain Name like string, globally unique
                          text string derived from a DNS name.
        macAddrAndUint(3) MAC address + 2-octet (unsigned) integer.
        charString(4)     RFC2579 DisplayString, except that the
```

```
                        character codes 0-31 (decimal) are not
                        used.
        ieeeReserved(xx)  Reserved for definition by IEEE 802.1
                        xx values can be [5..31] and [96..255]
        ituReserved(xx)   Reserved for definition by  ITU-T G.8013/Y.1731
                        xx values range from [32..63]
        ietfReserved(xx)  Reserved for definition by IETF.  xx values range
                        from [64..95].

        To support future extensions, the Dot1agCfmMaintDomainNameType
        textual convention SHOULD NOT be subtyped in object type
        definitions.  It MAY be subtyped in compliance statements in
        order to require only a subset of these address types for a
        compliant implementation.

        Implementations MUST ensure that Dot1agCfmMaintDomainNameType
        objects and any dependent objects (e.g.,
        Dot1agCfmMaintDomainName objects) are consistent.  An
        inconsistentValue error MUST be generated if an attempt to
        change an Dot1agCfmMaintDomainNameType object would, for
        example, lead to an undefined Dot1agCfmMaintDomainName value.
        In particular,
        Dot1agCfmMaintDomainNameType/Dot1agCfmMaintDomainName pairs
        MUST be changed together if the nameType changes.
       "
    REFERENCE
       "21.6.5, Table 21-18"
    SYNTAX      INTEGER {
                  none              (1),
                  dnsLikeName       (2),
                  macAddressAndUint (3),
                  charString        (4)
                }

Dot1agCfmMaintDomainName ::= TEXTUAL-CONVENTION
    STATUS      current
    DESCRIPTION
       "Denotes a generic Maintenance Domain Name.

        A Dot1agCfmMaintDomainName value is always interpreted within
        the context of a Dot1agCfmMaintDomainNameType value.  Every
        usage of the Dot1agCfmMaintDomainName textual convention is
        required to specify the Dot1agCfmMaintDomainNameType object
        that provides the context.  It is suggested that the
        Dot1agCfmMaintDomainNameType object be logically registered
        before the object(s) that use the Dot1agCfmMaintDomainName
        textual convention, if they appear in the same logical row.

        The value of a Dot1agCfmMaintDomainName object MUST always
        be consistent with the value of the associated
        Dot1agCfmMaintDomainNameType object. Attempts to set
        an Dot1agCfmMaintDomainName object to a value inconsistent
        with the associated Dot1agCfmMaintDomainNameType MUST fail
        with an inconsistentValue error.

        When this textual convention is used as the syntax of an
        index object, there may be issues with the limit of 128
        sub-identifiers specified in SMIv2, IETF STD 58.  In this
        case, the object definition MUST include a 'SIZE' clause
        to limit the number of potential instance sub-identifiers;
        otherwise the applicable constraints MUST be stated in
        the appropriate conceptual row DESCRIPTION clauses, or
        in the surrounding documentation if there is no single
        DESCRIPTION clause that is appropriate.

        A value of none(1) in the associated
        Dot1agCfmMaintDomainNameType object means that no Maintenance
        Domain name is present, and the contents of the
        Dot1agCfmMaintDomainName object are meaningless.

        See the DESCRIPTION of the Dot1agCfmMaintAssocNameType
        TEXTUAL-CONVENTION for a discussion of the length limits on
```

```
        the Maintenance Domain name and Maintenance Association name.

        ieeeReserved(xx)  Reserved for definition by IEEE 802.1
                          xx values can be [5..31] and [96..255]
        iccFormat(32)     ICC-based format as specified in ITU-T G.8013/Y.1731
        ituReserved(xx)   Reserved for definition by  ITU-T G.8013/Y.1731
                          xx values range from [33..63]
        ietfReserved(xx)  Reserved for definition by IETF
                          xx values range from [64..95]

        To support future extensions, the Dot1agCfmMaintAssocNameType
        textual convention SHOULD NOT be subtyped in object type
        definitions.  It MAY be subtyped in compliance statements in
        order to require only a subset of these address types for a
        compliant implementation.
```

```
        Implementations MUST ensure that Dot1agCfmMaintAssocNameType
        objects and any dependent objects (e.g.,
        Dot1agCfmMaintAssocName objects) are consistent.  An
        inconsistentValue error MUST be generated if an attempt to
        change an Dot1agCfmMaintAssocNameType object would, for
        example, lead to an undefined Dot1agCfmMaintAssocName value.
        In particular,
        Dot1agCfmMaintAssocNameType/Dot1agCfmMaintAssocName pairs
        MUST be changed together if the nameType changes.

        The Maintenance Domain name and Maintenance Association name,
        when put together into the CCM PDU, MUST total 48 octets or
        less.  If the Dot1agCfmMaintDomainNameType object contains
        none(1), then the Dot1agCfmMaintAssocName object MUST be
        45 octets or less in length.  Otherwise, the length of
        the Dot1agCfmMaintDomainName object plus the length of the
        Dot1agCfmMaintAssocName object, added together, MUST total
        less than or equal to 44 octets.

    REFERENCE
       "21.6.5.4, Table 21-19"
    SYNTAX      INTEGER {
                  primaryVid        (1),
                  charString        (2),
                  unsignedInt16     (3),
                  rfc2865VpnId      (4),
                  iccFormat         (32)
                }

Dot1agCfmMaintAssocName ::= TEXTUAL-CONVENTION
    STATUS      current
    DESCRIPTION
       "Denotes a generic Maintenance Association Name. It is the
        part of the Maintenance Association Identifier that is
        unique within the Maintenance Domain Name and is appended
        to the Maintenance Domain Name to form the Maintenance
        Association Identifier (MAID).

        A Dot1agCfmMaintAssocName value is always interpreted within
        the context of a Dot1agCfmMaintAssocNameType value.  Every
        usage of the Dot1agCfmMaintAssocName textual convention is
        required to specify the Dot1agCfmMaintAssocNameType object
        that provides the context.  It is suggested that the
        Dot1agCfmMaintAssocNameType object be logically registered
        before the object(s) that use the Dot1agCfmMaintAssocName
        textual convention, if they appear in the same logical row.

        The value of a Dot1agCfmMaintAssocName object MUST
        always be consistent with the value of the associated
        Dot1agCfmMaintAssocNameType object. Attempts to set
        an Dot1agCfmMaintAssocName object to a value inconsistent
        with the associated Dot1agCfmMaintAssocNameType MUST fail
        with an inconsistentValue error.

        When this textual convention is used as the syntax of an
        index object, there may be issues with the limit of 128
        sub-identifiers specified in SMIv2, IETF STD 58.  In this
        case, the object definition MUST include a 'SIZE' clause
        to limit the number of potential instance sub-identifiers;
        otherwise the applicable constraints MUST be stated in
        the appropriate conceptual row DESCRIPTION clauses, or
        in the surrounding documentation if there is no single
        DESCRIPTION clause that is appropriate.

                }

Dot1agCfmInterfaceStatus ::= TEXTUAL-CONVENTION
    STATUS      current
    DESCRIPTION
      "An enumerated value from the Interface Status TLV from the
       last CCM received from the last MEP. It indicates the status
       of the Interface within which the MEP transmitting the CCM
       is configured, or the next lower Interface in the Interface
       Stack, if the MEP is not configured within an Interface.

    isNoInterfaceStatusTLV(0)  Indicates either that no CCM has been
                          received or that no interface status TLV
                          was present in the last CCM received.

    isUp(1)               The interface is ready to pass frames.

    isDown(2)             The interface cannot pass frames.

    isTesting(3)          The interface is in some test mode.

    isUnknown(4)          The interface status cannot be determined
                          for some reason.

    isDormant(5)          The interface is not in a state to pass
                          frames but is in a pending state, waiting
                          for some external event.

    isNotPresent(6)       Some component of the interface is missing

    isLowerLayerDown(7)   The interface is down due to state of the
                          lower layer interfaces

        NOTE: A 0 value is used for isNoInterfaceStatusTLV, so that
              these code points can be kept consistent with new code
              points added to ifOperStatus in the IF-MIB.

    DESCRIPTION
       "Indicates what, if anything, is to be included in the Sender
        ID TLV transmitted in CCMs, LBMs, LTMs, and LTRs.  The valid
        values are:

        sendIdNone(1)      The Sender ID TLV is not to be sent.
        sendIdChassis(2)   The Chassis ID Length, Chassis ID
                           Subtype, and Chassis ID fields of  the
                           Sender ID TLV are to be sent.
        sendIdManage(3)    The Management Address Length and
                           Management Address of the Sender ID TLV
                           are to be sent.
        sendIdChassisManage(4) The Chassis ID Length, Chassis ID
                           Subtype, Chassis ID, Management Address
                           Length and Management Address fields are
                           all to be sent.
        sendIdDefer(5)     The contents of the Sender ID TLV are
                           determined by the corresponding
                           Maintenance Domain variable
                           (dot1agCfmMaCompIdPermission).

Dot1afCfmIndexIntegerNextFree ::= TEXTUAL-CONVENTION
    DISPLAY-HINT "d"
    STATUS      current
    DESCRIPTION
      "An integer that may be used as a new Index in a table.

       The special value of 0 indicates that no more new entries can
```

```
        be created in the relevant table.

        When a MIB is used for configuration, an object with this
        SYNTAX always contains a legal value (if non-zero) for an
        index that is not currently used in the relevant table. The
        Command Generator (Network Management Application) reads this
        variable and uses the (non-zero) value read when creating a
        new row with an SNMP SET.  When the SET is performed, the
        Command Responder (agent) MUST determine whether the value is
        indeed still unused; Two Network Management Applications may
        attempt to create a row (configuration entry) simultaneously
        and use the same value. If it is currently unused, the SET
        succeeds and the Command Responder (agent) changes the value
        of this object, according to an implementation-specific
        algorithm.  If the value is in use, however, the SET fails.
        The Network Management Application MUST then re-read this
        variable to obtain a new usable value.

        An OBJECT-TYPE definition using this SYNTAX MUST specify the
        relevant table for which the object is providing this
        functionality.
       "

-- ********************************************************************
-- The Default MD Level Table
-- ********************************************************************

dot1agCfmDefaultMdTable OBJECT-TYPE
    SYNTAX      SEQUENCE OF Dot1agCfmDefaultMdEntry
    MAX-ACCESS  not-accessible
    STATUS      deprecated
    DESCRIPTION
       "For each Bridge component, the Default MD Level Managed Object
        controls MHF creation for VIDs that are not attached to a
        specific Maintenance Association Managed Object, and Sender ID
        TLV transmission by those MHFs.

        For each Bridge Port, and for each VLAN ID whose data can
        pass through that Bridge Port, an entry in this table is
        used by the algorithm in 22.2.3 only if there is no
        entry in the Maintenance Association table defining an MA
        for the same VLAN ID and MD Level as this table's entry, and
        on which MA an Up MEP is defined.  If there exists such an
        MA, that MA's objects are used by the algorithm in
        22.2.3 in place of this table entry's objects.  The
        agent maintains the value of dot1agCfmDefaultMdStatus to
        indicate whether this entry is overridden by an MA.

        When first initialized, the agent creates this table
        automatically with entries for all VLAN IDs,
        with the default values specified for each object.

        After this initialization, the writable objects in this
        table need to be persistent upon reboot or restart of a
        device.

dot1agCfmMaNetTable OBJECT-TYPE
    SYNTAX      SEQUENCE OF Dot1agCfmMaNetEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
       "The Maintenance Association table.  Each row in the table
        represents an MA.  An MA is a set of MEPs, each configured
        with a single service instance.

        This is the part of the complete MA table that is constant
        across all Bridges in a Maintenance Domain, and across all
        components of a single Bridge.  That part of the MA table that
        can vary from Bridge component to Bridge component is contained
        in the dot1agCfmMaCompTable.

        Creation of a Service Instance establishes a connectionless
```

```
        association among the selected DSAPs.  Configuring a
        Maintenance association Endpoint (MEP) at each of the
        DSAPs creates a Maintenance Association (MA) to monitor
        that connectionless connectivity.  The MA is identified by a
        Short MA Name that is unique within the Maintenance Domain
        and chosen to facilitate easy identification of the Service
        Instance.  Together, the Maintenance Domain Name and the
        Short MA Name form the Maintenance Association Identifier
        (MAID) that is carried in CFM Messages to identify
        incorrect connectivity among Service Instances.  A small
        integer, the Maintenance association Endpoint Identifier
        (MEPID), identifies each MEP among those configured on a
        single MA (3.133, 18.2).

        This table uses two indices, first index is the index of the
        Maintenance Domain table.  The second index is the same as the
        index of the dot1agCfmMaCompEntry for the same MA.

        The writable objects in this table need to be persistent
        upon reboot or restart of a device.

    ::= { dot1agCfmMaCompEntry 6 }

-- ********************************************************************
-- The list of known MEPs for a given MA
-- ********************************************************************

dot1agCfmMaMepListTable OBJECT-TYPE
    SYNTAX      SEQUENCE OF Dot1agCfmMaMepListEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
        "List of MEPIDs that belong to this MA.

         12.14.6.1.3 specifies that a list of MEPIDs in all
         Bridges in that MA, but since SNMP SMI does not allow to
         state in a MIB that an object in a table is an array, the
         information has to be stored in another table with two
         indices, being the first index, the index of the table that
         contains the list or array.

         For all Bridges in which the same MAID {dot1agCfmMdFormat,
         dot1agCfmMdName, dot1agCfmMaNetFormat, and dot1agCfmMaNetName}
         is configured, the same set of dot1agCfmMaMepListIdentifiers
         MUST be configured in the Bridges' dot1agCfmMaMepListTables.
         This allows each MEP to determine whether or not it is
         receiving CCMs from all of the other MEPs in the MA.

         For example, if one were creating a new MA whose MAID were
         {charString, 'Dom1', charString, 'MA1'}, that had 2 MEPs, whose
         MEPIDs were 1 and 3, one could, in Bridge A:
          1. Get a new MD index d from dot1agCfmMdTableNextIndex.
          2. Create the Maintenance Domain {charString, 'Dom1'}.
          3. Get a new MA index a from dot1agCfmMdMaNextIndex [d].
          4. Create the Maintenance Association {charString, 'MA1'}.
          5. Create a new dot1agCfmMaMepListEntry for each of the MEPs
```

```
            in the MA: [d, a, 1] and [d, a, 3].
         6. Create one of the new MEPs, say [d, a, 1].
        Then, in Bridge B:
         7. Do all of these steps 1-6, except for using the other MEPID
            for the new MEP in Step 6, in this example, MEPID 3.
        Note that, when creating the MA, MEP List Table, and MEP
        entries in the second Bridge, the indices 'd' and 'a'
        identifying the MAID {charString, 'Dom1', charString, 'MA1'}
        may have different values than those in the first Bridge.

dot1agCfmMepTable OBJECT-TYPE
    SYNTAX      SEQUENCE OF Dot1agCfmMepEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
       "The Maintenance Association Endpoint (MEP) table.

        Each row in the table represents a different MEP.  A MEP is
        an actively managed CFM entity, associated with a specific
        DSAP of a Service Instance, which can generate and receive
        CFM PDUs and track any responses.  It is an endpoint of a
        single Maintenance Association, and is an endpoint of a
```

```
separate Maintenance Entity for each of the other MEPs in
the same Maintenance Association (3.133).

This table uses three indices. The first two indices are the
indices of the Maintenance Domain and MA tables, the reason
being that a MEP is always related to an MA and Maintenance
Domain.

The MEP table also stores all the managed objects for sending
LBM and LTM.

*LBM Managed objects

LBM Managed objects in the MEP table
enables the management entity to initiate
transmission of Loopback messages.  It will signal the MEP
that it SHOULD transmit some number of Loopback messages
and detect the detection (or lack thereof) of the
corresponding Loopback messages.

Steps to use entries in this table:

1) Wait for dot1agCfmMepTransmitLbmStatus value to be
   false.  To do this do this sequence:
   a. an SNMP GET for both SnmpSetSerialNo and
      dot1agCfmMepTransmitLbmStatus objects (in same SNMP
      PDU).
   b. Check if value for dot1agCfmMepTransmitLbmStatus is false.
      - if not, wait x seconds, go to step a above.
      - if yes, save the value of SnmpSetSerialNo and go
        to step 2) below
2) Change dot1agCfmMepTransmitLbmStatus value from false to
   true to ensure no other management entity will use
   the service. In order to not disturb a possible other NMS
   do this by sending an SNMP SET for both SnmpSetSerialNo
   and dot1agCfmMepTransmitLbmStatus objects (in same SNMP
   PDU,  and make sure SNmpSetSerialNo is the first varBind).
   For the SnmpSetSerialNo varBind, use the value that you
   obtained in step 1)a.. This ensures that two cooperating
   NMSes will not step on each others toes.
   Setting this MIB object does not set the corresponding
   LBIactive state machine variable.
3) Setup the different data to be sent (number of messages,
   optional TLVs,...), except do not set
   dot1agCfmMepTransmitLbmMessages.
4) Record the current values of dot1agCfmMepLbrIn,
   dot1agCfmMepLbrInOutOfOrder, and dot1agCfmMepLbrBadMsdu.
6) Set dot1agCfmMepTransmitLbmMessages to a non-zero value to
   initiate transmission of Loopback messages.
   The dot1agCfmMepTransmitLbmMessages indicates the
   number of LBMs to be sent and is not decremented as
   loopbacks are actually sent. dot1agCfmMepTransmitLbmMessages
   is not equivalent to the LBMsToSend state machine variable.
7) Check the value of dot1agCfmMepTransmitLbmResultOK to
   find out if the operation was successfully initiated or
   not.
8) Monitor the value of dot1agCfmMepTransmitLbmStatus.
   When it is reset to false, the last LBM has been transmitted.
   Wait an additional 5 seconds to ensure that all LBRs have
   been returned.
9) Compare dot1agCfmMepLbrIn, dot1agCfmMepLbrInOutOfOrder,
   and dot1agCfmMepLbrBadMsdu to their old values from step
   4, above, to get the results of the test.

*LTM Managed objects
The LTM Managed objects in the MEP table are used in a manner
similar to that described for LBM transmission, above. A SET
operation to the variable dot1agCfmMepTransmitLtmFlags
triggers the transmission of an LTM. Then, the variables
dot1agCfmMepTransmitLtmSeqNumber and
dot1agCfmMepTransmitLtmEgressIdentifier return the information
required to recover the results of the LTM from the

    SYNTAX      OCTET STRING (SIZE(8))
    MAX-ACCESS  read-create
    STATUS      current
    DESCRIPTION
       "Identifies the MEP Linktrace Initiator that is originating,
        or the Linktrace Responder that is forwarding, this LTM.
        The low-order six octets contain a 48-bit IEEE MAC address
        unique to the system in which the MEP Linktrace Initiator
        or Linktrace Responder resides.  The high-order two octets
        contain a value sufficient to uniquely identify the MEP
        Linktrace Initiator or Linktrace Responder within that system.

        For most Bridges, the address of any MAC attached to the
        Bridge will suffice for the low-order six octets, and 0 for
        the high-order octets.  In some situations, e.g., if multiple
        virtual Bridges utilizing emulated LANs are implemented in a
        single physical system, the high-order two octets can be used
        to differentiate among the transmitting entities.

        The value returned is undefined if
        dot1agCfmMepTransmitLtmResult is false.

-- ********************************************************************
-- NOTIFICATIONS (TRAPS)
-- These notifications will be sent to the management entity
-- whenever a MEP loses/restores contact with one or more other MEPs.
-- ********************************************************************

dot1agCfmFaultAlarm NOTIFICATION-TYPE
    OBJECTS     { dot1agCfmMepHighestPrDefect
                }
    STATUS      current
    DESCRIPTION
       "A MEP has a persistent defect condition. A notification
        (fault alarm) is sent to the management entity with the OID
        of the MEP that has detected the fault.

        Whenever a MEP has a persistent defect,
        it may or may not generate a Fault Alarm to warn the system
        administrator of the problem, as controlled by the MEP
        Fault Notification Generator State Machine and associated
        Managed Objects. Only the highest-priority defect, as shown
        in Table 20-1, is reported in the Fault Alarm.

        If a defect with a higher priority is raised after a Fault
        Alarm has been issued, another Fault Alarm is issued.

        The management entity receiving the notification can identify
        the system from the network source address of the
        notification, and can identify the MEP reporting the defect
        by the indices in the OID of the dot1agCfmMepHighestPrDefect
        variable in the notification:

           dot1agCfmMdIndex - Also the index of the MEP's
                              Maintenance Domain table entry
                              (dot1agCfmMdTable).
           dot1agCfmMaIndex - Also an index (with the MD table index)
                              of the MEP's Maintenance Association
                              network table entry
                              (dot1agCfmMaNetTable), and (with the MD
                              table index and component ID) of the
                              MEP's MA component table entry
                              (dot1agCfmMaCompTable).
           dot1agCfmMepIdentifier - MEP Identifier and final index
                              into the MEP table (dot1agCfmMepTable).

        TLV transmission by those MHFs.

        For each Bridge Port, and for each VLAN ID whose data can
        pass through that Bridge Port, an entry in this table is
        used by the algorithm in 22.2.3 only if there is no
        entry in the Maintenance Association table defining an MA
        for the same VLAN ID and MD Level as this table's entry, and
        on which MA an Up MEP is defined.  If there exists such an
        MA, that MA's objects are used by the algorithm in
        22.2.3 in place of this table entry's objects.  The
        agent maintains the value of ieee8021CfmDefaultMdStatus to
        indicate whether this entry is overridden by an MA.

        When first initialized, the agent creates this table
        automatically with entries for all VLAN IDs,
        with the default values specified for each object.

        After this initialization, the writable objects in this
        table need to be persistent upon reboot or restart of a
        device.

-- ********************************************************************

ieee8021CfmMaCompTable OBJECT-TYPE
    SYNTAX      SEQUENCE OF Ieee8021CfmMaCompEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
        "The Maintenance Association table.  Each row in the table
         represents an MA.  An MA is a set of MEPs, each configured
         with a single service instance.

         This is the part of the complete MA table that is variable
         across the Bridges in a Maintenance Domain, or across the
         components of a single Bridge.  That part of the MA table that
```

```
        is constant across the Bridges and their components in a
        Maintenance Domain is contained in the dot1agCfmMaNetTable.

        This table uses three indices, first index is the
        IEEE8021PbbComponentIdentifier that identifies the component
        within the Bridge for which the information in the
        ieee8021CfmMaCompEntry applies.  The second is the index of the
        Maintenance Domain table.  The third index is the same as the
        index of the ieee8021CfmMaNetEntry for the same MA.

        The writable objects in this table need to be persistent
        upon reboot or restart of a device.

   SYNTAX SEQUENCE OF Ieee8021TpmrPortDiscardDetailsEntry
   MAX-ACCESS         not-accessible
   STATUS             current
   DESCRIPTION
      "The TPMR frames discard details table.  Each row in
       the table represents a discarded frame on a TPMR port.
       By definition there are two ports per TPMR.

       This table is maintained as a FIFO.  A new entry is
       inserted in the first row, and existing entries are
       shuffled down, with the last entry being discarded.

       Because of the FIFO behavior, the relationship between
       the index and contents will change when an entry is
       added to the table.  This may result in apparent
       duplication of row content during a table traversal."

Ieee8021CnControlChoice
 ::= TEXTUAL-CONVENTION
    STATUS  current
    DESCRIPTION
       "This controls what other object selects the CND defense mode and
        the Congestion Notification Priority Value (CNPV) alternate
        priority for a CNPV in an end station or Bridge component, or
        for a CNPV on a particular Port in an end station or Bridge
        component.  It can take the following values:

        cpcAdmin(1) The CND defense mode and alternate priority are
                    controlled by the administrative variables in the
                    same table entry as this object.
        cpcAuto(2)  This Port or all Ports' CND defense modes are
                    controlled automatically, as indicated by
                    ieee8021CnPortPriAutoDefenseMode, and the
                    alternate priority by ieee8021CnComPriAutoAltPri.
        cpcComp(3)  This CND defense mode and alternate priority are
                    both controlled by ieee8021CnPortPriTable.
       "
    REFERENCE
       "32.3.1, 32.4.1, Table 32-2"
    SYNTAX  INTEGER {
        cpcAdmin(1),
        cpcAuto(2),
        cpcComp(3)
    }

Ieee8021CnDefenseMode
 ::= TEXTUAL-CONVENTION
    STATUS  current
    DESCRIPTION
       "For a given Congestion Notification Priority Value (CNPV), a
        port can operate in one of four CND defense modes.  The CND
```

```
        defense mode determines whether congestion notification is
        enabled or not, and if enabled, whether the port translates the
        CNPV to a non-CNPV value on input, and whether the port removes
        CN-TAGs on output.

        cptDisabled(1)       The congestion notification capability is
                             administratively disabled for this priority
                             value and port. This priority is not a CNPV.
                             The priority regeneration table controls the
                             remapping of input frames on this port for
                             this priority. CN-TAGs are neither added by
                             an end station nor stripped by a Bridge.
        cptInterior(2)       On this port and for this CNPV, the priority
                             parameters of input frames are not remapped,
                             regardless of the priority regeneration
                             table. CN-TAGs are not added by an end
                             station, and are removed from frames before
                             being output by a Bridge.
        cptInteriorReady(3)  On this port and for this CNPV, the priority
                             parameters of input frames are not remapped,
                             regardless of the priority regeneration
                             table. CN-TAGs can be added by an end
                             station, and are not removed from frames by
                             a Bridge.
        cptEdge(4)           On this port and for this CNPV, the priority
                             parameters of input frames are remapped to
                             an alternate (non-CNPV) value, regardless of
                             the priority regeneration table. CN-TAGs are
                             not added by an end station, and are removed
                             from frames before being output by a Bridge.

ieee8021CnCompntPriTable
 OBJECT-TYPE
```

```
    SYNTAX      SEQUENCE OF Ieee8021CnCompntPriEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
       "Each row in this table supplies default values for one
        Congestion Notification Priority Value for a whole Bridge
        component or end station.

        Creating a row in this table makes the priority value of
        ieee8021CnComPriPriority a
        Congestion Notification Priority Value.
        Deleting a row in this table makes the value in the deleted
        ieee8021CnComPriPriority no longer a
        Congestion Notification Priority Value.

        A  system SHALL NOT allow eight rows in this table
        to be created with the same value of
        ieee8021CnComPriComponentId; see the description of
        ieee8021CnComPriRowStatus.

        The contents of this table SHALL be maintained across a restart
        of the system.

-- ****************************************************************
-- The CCF per-CP table.  One table per end station or Bridge component.
-- One entry per Congestion Point.  An entry in this table controls one
-- Congestion Point (CP).
-- ****************************************************************

ieee8021CnCpTable
 OBJECT-TYPE
    SYNTAX      SEQUENCE OF Ieee8021CnCpEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
       "Each row in this table supplies values for one
        Congestion Point (CP).

        This table is indexed by component, port (interface), and
        an arbitrary CP index.  This arbitrary CP index is not
        necessarily the Congestion Point Identifier (CPID) carried in
        Congestion Notification Messages (CNMs).

        Creating an entry in ieee8021CnCompntPriTable can create an
        entry in this table, with the default values, on all ports in
        the Bridge component or end station.  Because more than one
        Congestion Notification Priority Value (CNPV) can flow
        through a single CP, the creation of an entry in
        ieee8021CnCompntPriTable does not necessarily create a new
        entry in this table.  An end station can have more than one
        CP for the same CNPV, so creating an entry in
        ieee8021CnCompntPriTable can create multiple entries in this
        table.

        Because each port in a Bridge component or end station can have
        a different relationship between CNPVs and CPs, the entries
        created or deleted on each port can be different.

        Deleting the last entry in ieee8021CnCompntPriTable for a
        CNPV passing through the CP controlled by this entry deletes
        the entry on some or all of the ports in the Bridge component
        or end station.

        Because each port in a Bridge component or end station can have
        a different relationship between CNPVs and CPs, the entries
        created or deleted on each port can be different.

        The relationship between ieee8021CnCpIndex
        values and CPs is an implementation dependent matter.

        The contents of this table SHALL be maintained across a restart
        of the system, except as noted in the description of
        ieee8021CnCpIfIndex.

 OBJECT-TYPE
    SYNTAX      Counter64
    UNITS       "centiseconds"
    MAX-ACCESS  read-only
    STATUS      current
    DESCRIPTION
       "This object returns the total number of centi-seconds that
        any of the Reaction Points (RPs) controlled by this entry
        has had its rpEnabled variable in the TRUE state.  That is,
        once each centi-second, this counter is incremented by the
        number of RPs this entry controls that are actively rate
        limiting output frames.

        Dividing the change in this object over a time interval by the
        length of the interval yields the average number of RPs active
        over that interval.  Dividing the change in this object by the
        change in ieee8021CnRpPortPriCreatedRps over that same time
        interval yields the average lifetime of an active RP during that
        interval.

-- ********************************************************************
-- The Reaction Point Group table.  One table per end station.
-- One entry per Reaction Point.
-- ********************************************************************

ieee8021CnRpGroupTable
 OBJECT-TYPE
    SYNTAX      SEQUENCE OF Ieee8021CnRpGroupEntry
    MAX-ACCESS  not-accessible
    STATUS      current
    DESCRIPTION
       "Each row in this table supplies values for one or more
        Reaction Points (RPs).  This table is indexed by component,
        port (interface), and an arbitrary RP index.

        Creating an entry in ieee8021CnCompntPriTable can create an
        entry in this table, with the default values, on all ports
        in the end station.  An end station can have more than one
        RP for the same Congestion Notification Priority Value
        (CNPV), so creating an entry in ieee8021CnCompntPriTable can
        create multiple entries in this table.

        Because each port in a Bridge component or end station can have
        a different relationship between CNPVs and RPs, the entries
        created or deleted on each port can be different.

        Deleting the an entry in ieee8021CnCompntPriTable for a
        CNPV passing through the RP controlled by this entry deletes
        entries on some or all of the ports in the end station.

        Because each port in an end station can have a
        different relationship between CNPVs and RPs, the entries
        created or deleted on each port can be different.
```

```
        The relationship between ieee8021CnRpgIdentifier
        values and RPs is an implementation dependent matter.

        The contents of this table SHALL be maintained across a restart
        of the system, except as noted in the description of
        ieee8021CnRpgIfIndex.

    }

ieee8021MirpV2PortEnabledStatus
 OBJECT-TYPE
    SYNTAX      TruthValue
    MAX-ACCESS  read-create
    STATUS      current
    DESCRIPTION
       "The state of MIRP operation on this port. The value
        true(1) indicates that MIRP is enabled on this port,
        as long as ieee8021PbbMirpEnableStatus is also enabled
        for this component. When false(2) but
        ieee8021PbbMirpEnableStatus is still
        enabled for the device, MIRP is disabled on this port.

        If MIRP is enabled on a VIP, then the MIRP Participant is
        enabled on that VIP's PIP.  If MIRP is enabled on none of the
```

```
        VIPs on a PIP, then the MIRP Participant on the PIP is
        disabled; any MIRP packets received will be silently discarded,
        and no MIRP registrations will be propagated from the PIP. A
        transition from all VIPs on a PIP false(2) to at least one VIP
        on the PIP true(1) will cause a reset of all MIRP state
        machines on this PIP.

        If MIRP is enabled on any port not a VIP, then the MIRP
        Participant is enabled on that port.  If MIRP is
        disabled on a non-VIP port, then MIRP packets received will be
        silently discarded, and no MIRP registrations will be
        propagated from the port.  A transition from false(2) to
        true(1) will cause a reset of all  MIRP state machines on a
        non-VIP port.

        The value of this object MUST be retained across
        reinitializations of the management system."

ieee8021STAdminControlList OBJECT-TYPE
    SYNTAX      OCTET STRING
    MAX-ACCESS  read-write
    STATUS      current
    DESCRIPTION
        "The administrative value of the ControlList parameter for the Port.
        The octet string value represents the contents of the control list as
        an ordered list of entries, each encoded as a TLV, as follows.
        The first octet  of each TLV is interpreted as an
        unsigned integer representing a gate operation name:
            0: SetGateStates
            1: Set-And-Hold-MAC
            2: Set-And-Release-MAC
            3-255: Reserved for future gate operations

        The second octet of the TLV is the length field,
        interpreted as an unsigned integer, indicating the number of
        octets of the value that follows the length. A length of
        zero indicates that there is no value
        (i.e., the gate operation has no parameters).

        The third through (3 + length -1)th octets encode the
        parameters of the gate operation, in the order that they
        appear in the definition of the operation
        in Table 8-6. Two parameter types are currently defined:

        - GateState:
            A GateState parameter is encoded in a single octet.
            The bits of the octet represent the gate states for the
            corresponding traffic classes; the MS bit corresponds
            to traffic class 7,
            the LS bit to traffic class 0. A bit value of 0 indicates
            closed; a bit value of 1 indicates open.

        - TimeInterval:
            A TimeInterval is encoded in 4 octets as a 32-bit
            unsigned integer, representing a number of nanoseconds.
            The first octet encodes the most significant 8 bits of the
            integer, and the fourth octet encodes the least
            significant 8 bits.

        The value of this object MUST be retained across
        reinitializations of the management system."

ieee8021PSFPFilterSpecificationList OBJECT-TYPE
    SYNTAX      OCTET STRING
    MAX-ACCESS  read-create
    STATUS      current
    DESCRIPTION
        "The FilterSpecificationList parameter contains a list of
        filter specifications associated with this stream filter.

        The octet string value represents the contents of the list as
        an ordered list of entries, each encoded as a TLV, as follows.

        The first octet  of each TLV is interpreted as an
        unsigned integer representing a filter specification type:
            0: Maximum SDU Size.
            1: Flow meter instance identifier.
            2-255: Reserved for future filter specification types

        The second and third octets of the TLV are the length field,
        interpreted as an unsigned integer, indicating the number of
        octets of the value that follows the length. A length of
        zero indicates that there is no value
        (i.e., the filter specification has no parameters).

        The fourth through (4 + length -1)th octets encode the
        parameters of the filter specification, as defined for each
        filter specification type.

        - Maximum SDU Size:
            A single SDU size parameter is encoded in four octets, and
            is interpreted as an unsigned integer value.

        - Flow meter instance identifier:
            A single flow meter instance identifier is encoded in
            four octets, and is interpreted as an unsigned integer value.

        The value of this object MUST be retained across
        reinitializations of the management system."

ieee8021PSFPAdminControlList OBJECT-TYPE
    SYNTAX      OCTET STRING
    MAX-ACCESS  read-create
    STATUS      current
    DESCRIPTION
        "The administrative value of the ControlList parameter for the gate.
        The octet string value represents the contents of the control list as
        an ordered list of entries, each encoded as a TLV, as follows.
        The first octet  of each TLV is interpreted as an
        unsigned integer representing a gate operation name:
            0: SetGateAndIPV
            1-255: Reserved for future gate operations
```

```
        The second octet of the TLV is the length field,
        interpreted as an unsigned integer, indicating the number of
        octets of the value that follows the length. A length of
        zero indicates that there is no value
        (i.e., the gate operation has no parameters).

        The third through (3 + length -1)th octets encode the
        parameters of the gate operation, in the order that they
        appear in the definition of the operation
        in Table 8-4. Three parameter types are defined:

        - StreamGateState:
            A GateState parameter is encoded in a single octet, and
            is interpreted as an integer value.
            The value 1 indicates open; the value 2 indicates closed.

        - IPV:
            An IPV is encoded in four octets as a 32-bit
            signed integer. A negative denotes the null value;
            zero or positive values denote internal priority values.

        - TimeInterval:
            A TimeInterval is encoded in 4 octets as a 32-bit
            unsigned integer, representing a number of nanoseconds.
            The first octet encodes the most significant 8 bits of the
            integer, and the fourth octet encodes the least
            significant 8 bits.
        - IntervalOctetMax:
            An integer representing the maximum number of MSDU octets
            that are permitted to pas the gate during the specified
            TimeInterval. If this parameter is omitted, there is
            no maximum.

        The value of this object MUST be retained across
        reinitializations of the management system."

    MAX-ACCESS  read-only
    STATUS      current
    DESCRIPTION
        "This attribute provides the minimum delay independent
        from frame length for a frame to forward from ingress
        port to egress port.

        The delay begins when the message timestamp point of the
        ingress frame passes the reference plane marking the
        boundary between the network media and PHY. The delay
        ends when the message timestamp point of the egress
        frame passes the reference plane marking the boundary
        between the network media and PHY. The message timestamp
        point is specified by IEEE Std 802.1AS for various media,
        near the start of the frame.

        Note: This delay includes all aspects of length-independent
        delay for a frame that is forwarded, including handling of
        error conditions."
    REFERENCE   "12.32.1.1"

ieee8021TsnRemoteMgmtMsrpMrpExternalControl OBJECT-TYPE
    SYNTAX      TruthValue
    MAX-ACCESS  read-write
    STATUS      current
    DESCRIPTION
        "This attribute is used to indicate, whether MRP
        attributes are propagated on the MRP Participant,
        according to the specifications for MRP Attribute
        Propagation (MAP) and specifications of the
        MRP Application. When true(1), the MRP Participant is
        removed from the MRP Application's MAP Context. The
        MRP Participant performs all other aspects of MRP,
        including MRP operation, MRP specifications, and
        MRPDU encodings. The application component stores MAD
        indications for registration received on the Port,
        and invokes MAD requests for declarations on the Port.
        When false(2), MRP attributes propagate on the
        MRP Participant according to the specifications for
        MRP Attribute Propagation (MAP) and specifications of
        the MRP Application. Ports with the externalControl
        attribute false(2) are considered as candidates for
        the MRP Application's MAP Context. The remaining
        attributes of this subtree are ignored by Ports with
        the externalControl attribute false(2).
        This managed object applies to the MSRP application.
        A table is provided for each MAP Context (VLAN ID)."

18. Principles of Connectivity Fault Management operation

Connectivity Fault Management (CFM) comprises capabilities for detecting, verifying, and isolating connectivity failures in Virtual Bridged Networks. These capabilities can be used in networks operated by multiple independent organizations, each with restricted management access to each other's equipment.

CFM is designed to be transparent to the customer data transported by a network and to be capable of providing maximum fault coverage. Accordingly, CFM Entities (Clause 19) are specified as shims that make use of and provide the ISS or EISS (IEEE Std 802.1AC, 6.8, 6.17) at SAPs within the network. They can, in principle, be added between any of the other media-independent protocol entities that compose a Bridge Port, without requiring changes to those entities. Customer data is forwarded transparently by CFM Entities while CFM PDUs are generated and processed as specified in Clause 20. The formats of the various CFM PDUs are described in Clause 21, and the creation and placement of CFM Entities in Bridges are specified in Clause 22.

This clause provides the context necessary to understand each of the CFM protocols, and how CFM Entities in Bridges are selected and configured as Maintenance Points (MPs, 19.1) to participate in and operate those protocols.

CFM introduces the following concepts to support multiple independent operators, each supporting service instances for multiple independent customers:

a) A Maintenance Domain (18.1) is a part of a network that is controlled by a single operator and used to support connectivity between the Domain Service Access Points (DoSAPs, 18.1) that bound the Maintenance Domain.
b) A Maintenance Domain Level (MD Level, 18.3), carried in CFM PDUs, allows each of an operator's customers also to use CFM and to function as an operator if desired, multiplexing provided service instances over its own connectivity.
c) A Maintenance Association (MA, 18.2) is created by configuring CFM Entities that support an individual service instance's DoSAPs as MA Endpoints (MEPs), and is used to monitor connectivity provided by that instance through the Maintenance Domain.

MP (19.1) configuration of CFM Entities supports the hierarchical nesting of Maintenance Domains. The DoSAPs for a given service instance are Intermediate Service Access Points (ISAPs) for MAs monitoring connectivity through an enclosing Maintenance Domain. When a MEP is configured, a MA Intermediate Point (MIP) can also be configured at the appropriate level for its immediately enclosing Maintenance Domain. Below the innermost Maintenance Domain, every physical LAN can serve as an implied Maintenance Domain, and every Bridge Port as an implied MEP. In the innermost Maintenance Domain, every Bridge Port is an ISAP and can be configured with a MIP.

Maintenance Domains are nested, not overlapped. That is, if a given DoSAP for service instance 1 in Maintenance Domain *x* is an ISAP for Maintenance Domain *y*, then all DoSAPs for service instance 1 in Maintenance Domain *x* are either ISAPs or DoSAPs for Maintenance Domain *y*, and no other Maintenance Domain. Conformance to this rule is not a condition for the correct operation of CFM. Rather, if this rule is violated, then CFM will detect the violation as an error condition, whatever the intentions of the administrators.

The information about individual service instances that is configured and recorded within a network to support CFM is entirely associated with MEPs, and thus scales linearly with the number of SAPs provided to customers. The transmission of CFM PDUs is stimulated by state machines associated with MEPs as are actions taken that require recording information from received PDUs. MIPs can add, check, and respond to information in received PDUs, thus supporting discovery of paths among MEPs and location of faults along those paths. MIPs can be configured per Maintenance Domain, thus allowing the amount of MIP configuration information to scale linearly with the size of the network, and is thus a constant function of the

ability of the network to support those MIPs, rather than being a product of the number of service instances supported. In contrast each MEP is associated with a SAP that provides access to a single service instance.

CFM functions are partitioned as follows:

— Path discovery
— Fault detection
— Fault verification and isolation
— Fault notification
— Fault recovery

Path discovery uses the Linktrace protocol (20.3) to determine the path taken to a target MAC address, MIP by MIP, from one MEP to another MP across an MA. This target MAC address can be that of a MIP, a MEP, or any other individual MAC address. A Linktrace Message (LTM, 20.3.1) is transmitted from a MEP to its neighboring MIPs, and from MIP to MIP, to the MP terminating the path. Each MIP along the path and the terminating MP return unicast Linktrace Replies (LTR, 20.3.2) to the originating MEP. LTMs are triggered by administrative action. The replies are cataloged by the originating MEP for examination by the administrator.

Fault detection uses the Continuity Check protocol (20.1) to detect both connectivity failures and unintended connectivity between service instances. Each MEP can periodically transmit a Continuity Check Message (CCM) announcing the identity of the MEP and its MA, and tracks the CCMs received from the other MEPs. All connectivity faults that can misdirect a CCM show up as differences between the CCMs received and the MEP's configured expectations. The state of the tracked CCMs is available to the administrator for examination.

Fault verification and fault isolation are administrative actions, typically performed after fault detection. Fault verification can also confirm successful initiation or restoration of connectivity. The administrator uses the Loopback protocol (20.2) to perform fault verification. A MEP can be ordered to transmit a Loopback Message (LBM, 20.2.1) to a MEP or MIP in the MA, whose MAC address can be discovered from CCMs (MEPs only) or LTMs/LTRs (MEPs or MIPs). The receiving MP responds by transforming the LBM into a unicast Loopback Reply (LBR, 20.2.2) sent back to the originating MEP. That MEP records the responses for examination by the administrator.

Fault notification is provided by a MEP that has detected a connectivity fault in its MA, because expected CCMs were not received, because unexpected or invalid CCMs were received, or because a CCM carried a notification of the failure of its associated Bridge Port. A single fault may be detected by multiple MEPs and may result in the generation of multiple Fault Alarms. In the absence of alarm suppression mechanisms in CFM, network management systems receiving such Fault Alarms can deploy other means to identify if a Fault Alarm identifies the primary fault for which a fault corrective action can be initiated, or represents a secondary fault for which no corrective action can be taken.

For VLANs, fault recovery is provided by the active topology protocols of Clause 13 while fault recovery for TESIs is provided by the Protection Switching mechanisms of 26.10. Fault recovery actions performed by the network administrator, such as the correction of configuration errors or replacement of failed components, are outside the scope of this standard.

18.1 Maintenance Domains and DoSAPs

A "domain" may be defined as a network or part of a network that is capable of offering connectivity to systems outside this region. It comprises a set of DoSAPs at which the domain is capable of or intended to offer connectivity to systems outside the domain. Each DoSAP is an instance either of the EISS or of the

ISS. A Maintenance Domain is then a domain or part of a domain for which faults in connectivity are to be managed.

A Maintenance Domain is, or is intended to be, fully connected internally. That is, a DoSAP associated with a Maintenance Domain has connectivity to every other DoSAP in the Maintenance Domain, in the absence of faults. It is, in principle at least, capable of connecting (i.e., supporting service between) any of its DoSAPs. The factors (apart from faults) that can prevent desired connectivity are second-order, e.g., exhaustion of resources that would support a proposed connection, an administrative decision to limit multipoint services, misconfiguration of security parameters, unwillingness of customers or attached Maintenance Domains to use a particular connection configuration. The purpose of CFM is to monitor and diagnose the ability of a Maintenance Domain to meet its operators' intentions for connectivity, as expressed in the configuration of CFM.

Figure 18-1 illustrates a single Maintenance Domain, consisting of five Bridges, from the point of view of an operator. The operator has six DoSAPs to offer to customers.

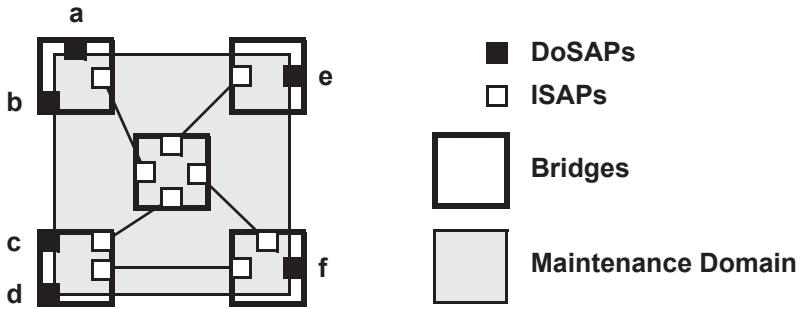

Figure 18-1—One Maintenance Domain: operator's view

Each Maintenance Domain can be separately administered. Each Maintenance Domain is assigned a Maintenance Domain Name. This should be chosen to be unique among all those used or available to an operator, and to facilitate easy identification of administrative responsibility for the Maintenance Domain. CFM PDU formats support the creation of Maintenance Domain Names that are unique over the domain for which CFM is to protect against accidental concatenation of service instances. Ideally, these names are globally unique.

There are a number of methods to fulfill the requirements to both maintain connectivity within, and control access to, a Maintenance Domain. A Maintenance Domain can be, for example,

a) An MST Region, identified and kept separate from other Maintenance Domains, by its MST Configuration Name (8.9.2, 13.8).
b) A number of such MST Regions (13.5.3), interconnected via the CIST (13.5.2), and kept separate from other Maintenance Domains by configuring the managed objects controlling the CIST topology.
c) An entire Virtual Bridged Network, and kept separate from other Maintenance Domains by means not specified in this standard.
d) A subset of the DoSAPs of a VLAN Bridged Network, assigned to the use of a particular higher-level provider among many.
e) A subset of the DoSAPs of the concatenated network in item c).
f) A single physical link between two providers or between a provider and a customer.
g) A single VLAN on a single physical link between two providers or between a provider and a customer.

18.2 Service instances and MAs

When a network administrator configures a service instance for a customer, the network administrator configures some number of the DoSAPs to be accessible by that customer, assigning whatever identifiers the systems require to segregate that service instance from others supported by that Maintenance Domain (e.g., VIDs), as well as configuring other service properties (such as bandwidth profiles) for the DoSAPs. Creation of a service instance establishes a connectionless connectivity (IEEE Std 802.1AC) among the selected DoSAPs.

Configuring a MEP at each of the DoSAPs of a service instance creates an MA to monitor that connectionless connectivity. The MA is identified by a Short MA Name that is unique within the Maintenance Domain. Together, the Maintenance Domain Name and the Short MA Name form the Maintenance Association Identifier (MAID) that is carried in CFM PDUs to identify inadvertent connections among MEPs. A small integer, the MA Endpoint Identifier (MEPID) uniquely identifies each MEP among those configured on a single MA.

NOTE 1—In order to accommodate the requirements of service providers as expressed in ITU-T G.8013/Y.1731, the Maintenance Domain Name can be configured to be null, in which case the Short MA Name needs to be globally unique, in order to provide complete protection against the accidental concatenation of service instances. Suitable choices for globally unique Short MA Names are defined in ITU-T G.8013/Y.1731.

Figure 18-2 illustrates a single service instance created from the Maintenance Domain of Figure 18-1, again from the point of view of an operator. It offers four DoSAPs to a customer (C1). Each DoSAP is marked with its MEPID.

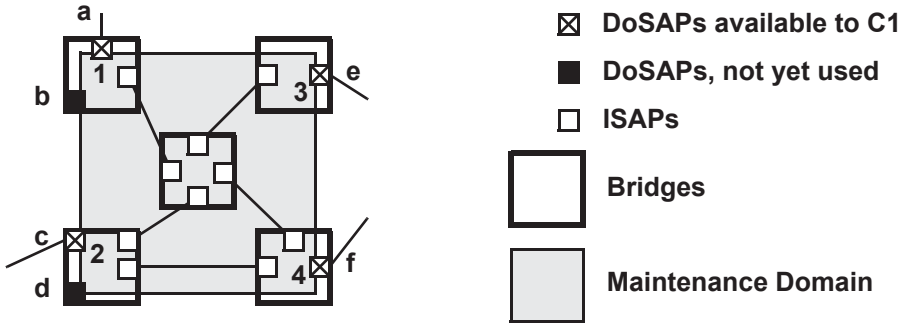

Figure 18-2—One service instance: operator's view

Figure 18-3 illustrates that same service instance from the point of view of customer C1. The customer has four items of customer equipment attached to the four DoSAPs 1–4. The means by which the operator connects the four DoSAPs to create the service instance are invisible to the customer.

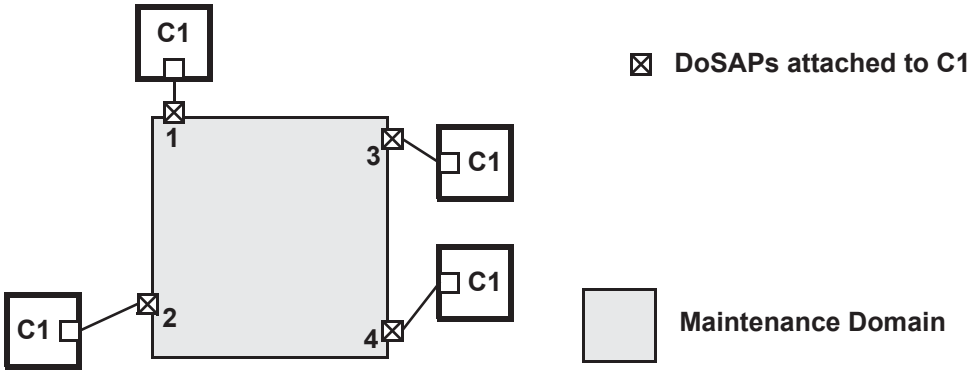

Figure 18-3—One service instance: customer's view

NOTE 2—The term “service instance” has been used to mean an “end-to-end service supplied to a customer.” One cannot predict whether an apparently end-to-end service instance will be used by a customer to create another service instance at a still higher level to yet another customer. Therefore, no specific term is provided by this standard to label an “end-to-end” service instance.

The CFM protocol state machines and variables (see Clause 20) are used by MEPs to conduct protocol exchanges within a Maintenance Domain. Each MIP functions symmetrically with respect to the SAPs of its containing MA and service instance, and is modeled as comprising two MIP Half Functions (MHFs). Figure 18-4 specifies the symbols used for MEPs, MHFs, and MIPs in this standard, e.g., in Figure 18-7.

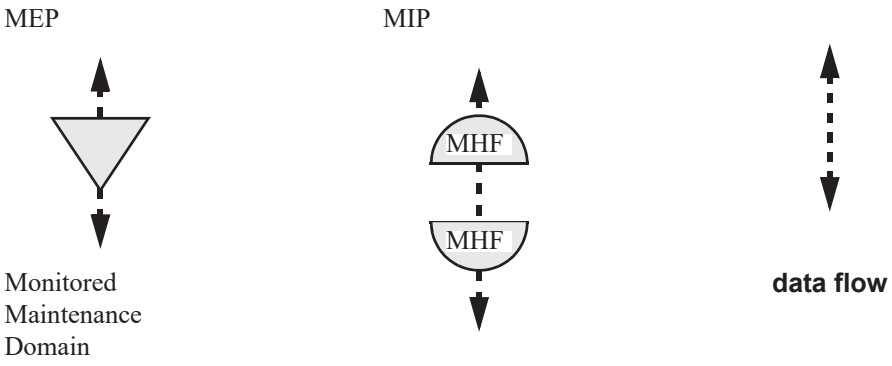

Figure 18-4—MEP and MIP Symbols

18.3 Maintenance Domain Levels

A Maintenance Domain can provide service instances to an enclosing Maintenance Domain or utilize service instances provided by an enclosed Maintenance Domain. An explicit Maintenance Domain Level (MD Level) is included in CFM PDUs to indicate the nesting relationships among Maintenance Domains, because systems can be organized into Maintenance Domains as administrative needs dictate, without necessarily adding headers to data frames to enforce a layered organization.

As part of the nested decomposition facility provided by Maintenance Domains, the CFM protocols hide information. The components of a given Maintenance Domain interior to the DoSAPs presented to the enclosing Maintenance Domain are invisible, through the CFM protocols and managed objects, to the Maintenance Domains enclosing that given Maintenance Domain, except for configured points of visibility. No part of a Maintenance Domain lower than (nested within) a given Maintenance Domain is unintentionally visible to any higher Maintenance Domain. No part of a Maintenance Domain is ever visible to any Maintenance Domain except its immediately higher (enclosing) Maintenance Domain. This enables the separation of responsibility for network administration. The administrator of an end-to-end service on the largest scale can be insulated from the administration of the networks comprising that service, and so on, in principle, down to the administration of individual LANs. This prevents, for example, a customer from learning the internal topology of an operator’s network.

In order to facilitate the diagnosis of connectivity failures, an administrator can make a DoSAP visible as an ISAP to the immediately enclosing Maintenance Domain by configuring it as a MIP. The diagnostic functions provided by CFM detect connectivity failures between any pair of MEPs in an MA. The MIPs allow these failures to be isolated to smaller segments of the network; loss of connectivity between a pair of MIPs corresponds to a MEP connectivity failure at a lower MD Level. In the lowest Maintenance Domains, the MIPs can be configured on individual Bridge Ports.

Figure 18-5 illustrates the nesting of Maintenance Domains, service instances, and MAs. It illustrates nested service instances, each configured with one MA in a Maintenance Domain. There are seven Maintenance Domains, and hence seven service instances illustrated. At the (white) "provider" MD Level, the service instance is offered to a single "customer" C1. That customer creates a (gray) service instance of his own, configured with an MA that verifies the integrity of the service instance offered by the provider. Several levels of nested Maintenance Domains are shown:

a) Covering the widest physical extent, a Maintenance Domain (and MA and service instance) at the customer MD Level has a MEP in each of four devices labeled C1 in Figure 18-5. The four DoSAPs a, b, g, and h can be configured as MIPs for this MA.

b) Covering the physical range corresponding to the limits of the end-to-end provider's network are the MEPs a, b, g, and h belonging to the provider MD Level. The four DoSAPs c, d, e, and f can be configured as MIPs for this MA.

c) Each of the two operator networks has a Maintenance Domain at the operator MD Level. These DoSAPs are marked a through h. The unlabeled SAPs in both operators' Maintenance Domains can be configured as MIPs for their respective MAs.

d) Three "physical" layer Maintenance Domains are shown as well. (Two are labeled "PMDL," for "physical MD Level.") Note that not all physical links are given Maintenance Domains.

   1) A network of devices is being used, in some unspecified fashion, to offer the operators' Bridges an emulated shared-medium LAN with four DoSAPs. A Maintenance Domain has been created to verify the connectivity of that LAN.

NOTE—This central emulated LAN could equally be a network of Bridges that are separated via nonstandard configuration from the operator clouds on either side, a network of PBBs, a network of Ethernet over SONET circuits with a central interconnect device, or an ATM Emulated LAN.[33]

   2) Physical-level Maintenance Domains have been created at the edge of the network (on the left side) to monitor two LANs, perhaps because they include Repeaters or are otherwise unreliable.

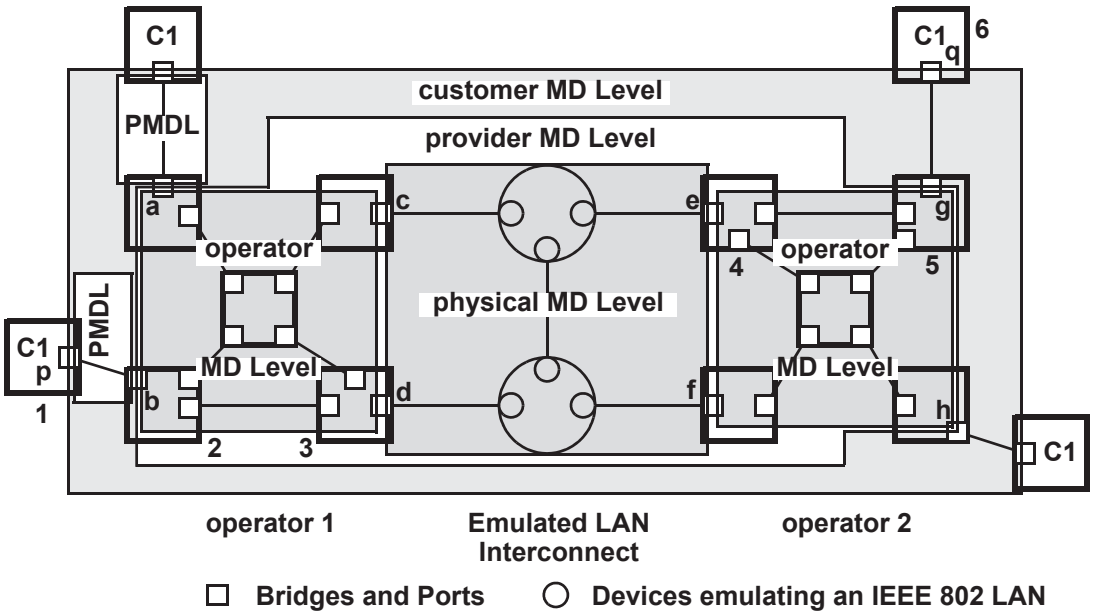

Figure 18-5—MAs: one service instance in a provider network

[33] See ATM Forum af-lane-0021.000; "LAN Emulation over ATM 1.0"; https://www.broadband-forum.org/ftp/pub/approved-specs/af-lane-0021.000.pdf.

Figure 18-6 expands the upper right corner of Figure 18-5, including Bridges 4 and 5 and device 6. Examining device 6 (C1), readers can see that the highest MA, at the "customer" MD Level, requires a MEP in its Port q. The side of the DoSAP of this service instance that offers access to the service instance faces the center of device 6, just like the service offered by a LAN. On the other hand, in Port g, there are two service instances, each with a MEP: the white service instance at the provider MD Level, and the gray service instance at the operator MD Level. Neither of these service instances include the wire attached to Port g. Thus, ensuring the proper operation of the LAN connecting Port q to Port g is the responsibility of the MA at the customer MD Level, and not the other MAs. Port e has two MEPs, one facing in each direction.

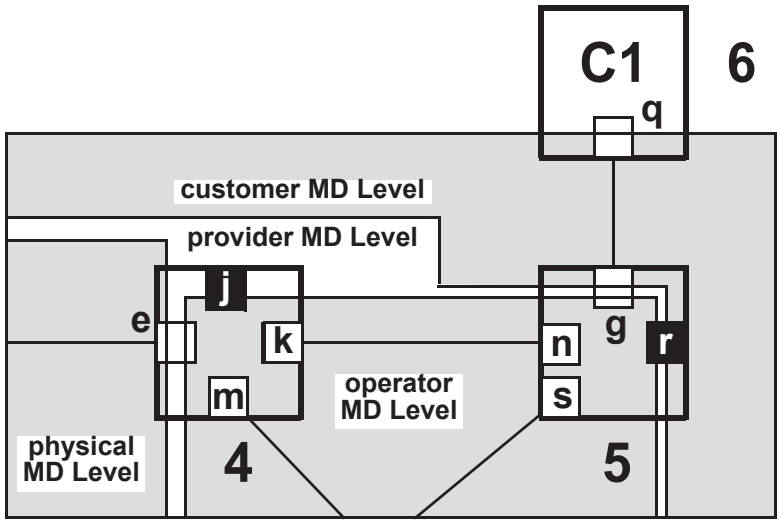

Figure 18-6—MAs: Expansion of Figure 18-5

Port g in Figure 18-6 also is an example of the fact that only the MD Level distinguishes the provider and operator Level Maintenance Domains at Port g. The single service instance in the example network shown in Figure 18-5 and Figure 18-6 is carried on a single VLAN with a single VID through the right-hand operator's Maintenance Domain. Within that Maintenance Domain, it cannot be distinguished whether a data frame on that VID belongs to the operator, provider, or customer Maintenance Domain; it belongs to all of them. However, the MD Level permits CFM PDUs to be associated with different Maintenance Domains even when they share the same VID.

Port j and Port r have been added to Figure 18-6; they are not present in Figure 18-5. Both represent DoSAPs that have not been configured to support either a service instance or an MA. For the integrity of the network to be ensured by CFM, these DoSAPs should be configured to be Disabled.

Ports k, m, n, and s can be configured as ISAPs for the gray service instance, providing a MIP at the operator MD Level. Port e can be configured with a MIP for the provider MD Level, and Port g with a MIP for the customer MD Level.

Figure 18-7 illustrates the use of MD Levels to allow the use of CFM by a user of connectivity provided by two bridged Maintenance Domains and by the operators of each of those Maintenance Domains. It illustrates a vertical slice through Figure 18-5, including two of the customer's devices, and the path through the network connecting them. One can see from Figure 18-7 why MD Levels are required to identify CFM PDUs; there would otherwise be no way for Bridge Port b, for example, to tell whether a given CFM PDU is to be sunk (MD Levels 2 or 3) or passed (MD Level 5).

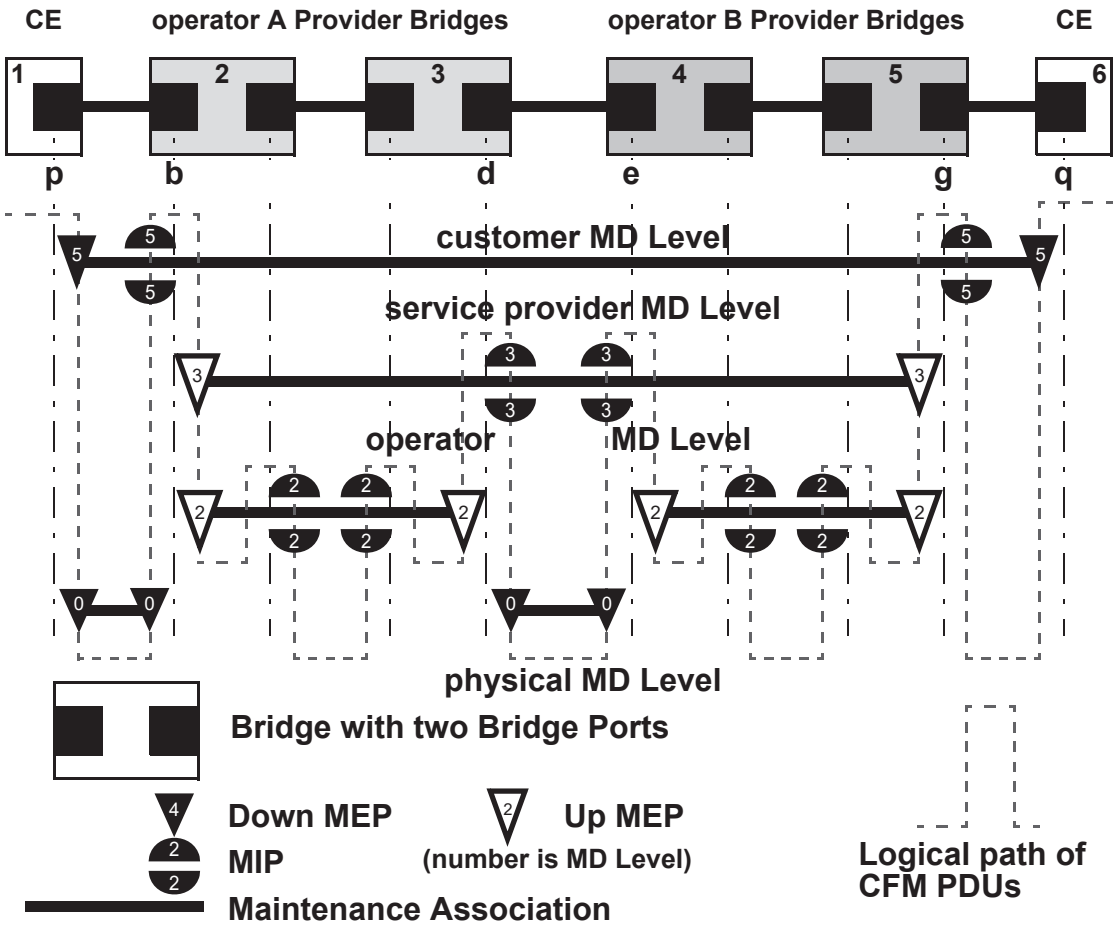

Figure 18-7—MEPs, MIPs, and MD Levels

Assignment of numerical MD Levels to the “customer” role, the “service provider” role, or the “operator” MD Levels is somewhat arbitrary, since those terms imply business relationships that cannot be standardized. See J.3 for a more detailed discussion of the assignment of MD Levels.

19. CFM entity operation

This clause specifies:

a) How the MPs that instantiate a CFM MA attach to ISS-SAPs or EISS-SAPs (19.1).
b) How MPs are addressed in networks (19.4).
c) The architecture of MEPs (19.2), MIPs (19.3), MHFs (19.3), Linktrace Output Multiplexers (LOMs, 19.5), and Linktrace Responders (19.6), including their identification, addressing, and decomposition into components that provide the CFM functions.

NOTE—Clause 18 introduces the principles of CFM operation and the network architectural concepts that support it. Clause 20 specifies the protocols operated by the components of each MP, and Clause 21 specifies the PDU formats used by those protocols. The use of CFM within systems and networks is further described in Clause 22.

The models of operation in this clause provide a basis for specifying the externally observable behavior of MEPs and MIPs, and are not intended to place additional constraints on implementations; these can adopt any internal model of operation compatible with the externally observable behavior specified. Conformance of equipment to this standard is purely in respect of observable protocol.

19.1 Maintenance Points (MPs)

The primary CFM protocol shims are called Maintenance Points (MPs). (See 19.6 for the other CFM protocol shim.) An MP can be either a MEP or an MHF. (See also 19.5 for a third type of CFM shim.) A MEP or an MHF each have two principle SAPs, an Active SAP, through which CFM PDUs produced and consumed by the MP are exchanged, and a Passive SAP, through which data frames and unprocessed CFM PDUs pass. Figure 19-1 illustrates the principle SAPs, and the symbols used for MEPs, MIPs, and MHFs in other figures, e.g., Figure 22-1. Note that an MP can be a Down MP or an Up MP, depending on whether the Passive SAP is above or below the Active SAP, respectively, in a shim diagram.

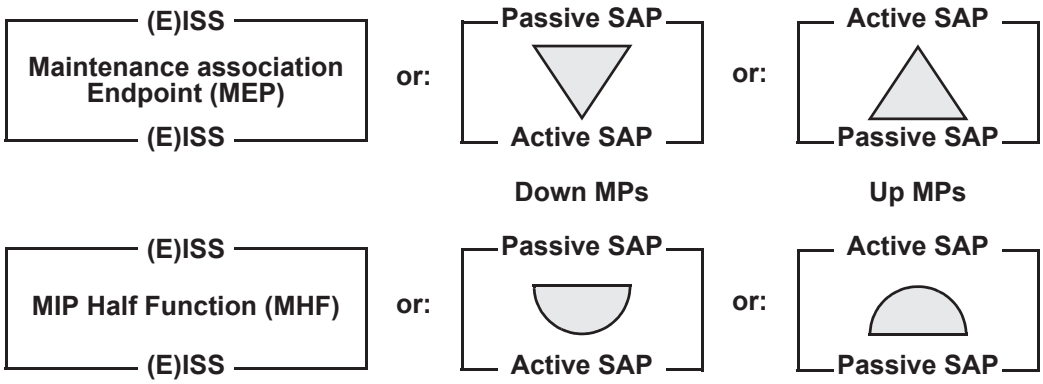

Figure 19-1—CFM Protocol shims

NOTE—The difference between Up MPs and Down MPs is explained more fully in 19.2.3 and 22.1.1.

19.2 MA Endpoints (MEPs)

A MEP can be created in either a Bridge Port (22.2) or an end station attachment to a LAN.

19.2.1 MEP identification

A MEP is associated with exactly one MA. It is identified for management purposes by two parameters, although other, additional parameters are used to manage the MEP:

a) The MAID, identifying the MA
b) A MEPID specific to this MEP

The MEP is identified for data forwarding purposes by:

c) A set of VIDs, including a Primary VID, inherited from the MA; or
d) An I-SID in the case of a Backbone Service Instance MA; or
e) A set of 3-tuples <ESP-DA, ESP-SA, ESP-VID> inherited from the MA when the MA is associated with a TESI; or
f) A SEG-ID inherited from the MA when the MA is associated with an Infrastructure Segment.

From the MA, the MEP inherits a Maintenance Domain, and from this it inherits:

g) A Maintenance Domain Level (MD Level), inherited from its Maintenance Domain and
h) One of the following inherited from its MA:
    1) A Primary VID or
    2) an I-SID in the case of a backbone service instance or
    3) a TE-SID in the case of a TESI or
    4) a SEG-ID in the case of an Infrastructure Segment

A MEP is associated with two Bridge Ports. For a Down MEP, both associations are with the same Bridge Port. For an Up MEP, the two associations can be with either the same, or with different, Bridge Ports (see 19.4, J.6). The two Bridge Ports are:

i) The Bridge Port on which the MEP is configured.
j) The Bridge Port on which the MEP is implemented, and from which it inherits its individual MAC address.

The set of MEPs configured with identical values for MAID define an MA. Thus, one can say that the MA, and not the MEPs, possesses this parameter. However, an MA is a diffuse entity that can be spread among a number of geographically separated Bridges. Each Bridge has its own Maintenance Association managed object for an MA, from which its MEP's MAID, MD Level, and Primary VID, I-SID, series of <ESP-DA, ESP-SA, ESP-VID> 3-tuples, or SEG-ID are derived. In the case of a VLAN-associated MA, the selection of which of the MA's VIDs is the Primary VID can be overridden for a specific MEP. Although this information can be incorrectly configured (i.e., configured differently than some other Bridge), the Maintenance Association managed object ensures the uniform configuration of MEPs in a single Bridge.

Each individual MEP is configured with a MEPID that is unique within that MA. Again, the Maintenance Association managed object helps to maintain uniqueness, as it ties together the configuration parameters of the MEPs in a single Bridge and the same MA and ensures the uniqueness of the MEPIDs, at least in that Bridge.

The MAID can take a number of forms (see 21.6.5.1), including a Domain Name-based string. To prevent incorrect operation in the face of unanticipated connections among systems, the MAID is unique over the domain for which CFM is to provide such protection. If the MAID is globally unique, then that domain is global. CFM can detect connectivity errors only over a set of MEPs in which MAIDs are unique.

The MEPID is an integer in the range 1–8191. It provides each MEP with the unique identity required for the MEPs to verify the correct connectivity of the MA.

NOTE—The range of the MEPID has been chosen to be large enough to accommodate most network needs, but small enough to be used as an index into a table of remote MEPs, and not require a table lookup, in a MEP Continuity Check Receiver (19.2.8) implemented in hardware.

19.2.2 MEP functions

The MEP:

a) Periodically transmits CCMs according to the managed objects defined in item e) in 12.14.6.1.3.
b) Validates received CFM PDUs as specified in 20.1, 20.2, 20.3, and 20.51.
c) Discards those CFM PDUs at a lower MD Level to that configured in the MEP (20.7.1).
d) Transmits LBMs and receives LBRs as defined in 20.2, according to the managed objects defined in 12.14.7.3.
e) Transmits LTMs, and transmits and receives LTRs as defined in 20.3, according to the managed objects defined in 12.14.7.4.
f) Responds to LBMs with LBRs as defined in 20.2.2.
g) Responds to LTMs with LTRs as defined in 20.3.2.
h) Maintains the MEP CCM Database as defined in 20.1.3.
i) May maintain the MIP CCM Database as defined in 20.1.3.
j) Maintains the variables in 20.9.

a) May decapsulate and transmit the payload of received Send Frame Messages (SFMs) (29.2.6).
b) May pass the received Reflected Frame Messages (RFMs) to RFM-Receiver (29.2.4).

Although defined as having either ISS or EISS interfaces, a MEP is highly constrained in its use of the EISS. Specifically,

c) Every frame passing through the MEP, in either direction, is emitted with its vlan_identifier and drop_eligible parameters unchanged from the value received.
d) All PDUs generated by the MEP, namely CCMs, LBMs, LBRs, LTMs, and LTRs, use the MEP's configured Primary VID as the vlan_identifier parameter.

19.2.3 MEP architecture

Figure 19-2 illustrates the component entities of a MEP. Entities that simply pass, redirect, or filter frames without altering them, and that have no internal state, are shown with dashed outlines; those that generate or transform frames, or that have an internal state, are shown with continuous outlines. State machines describing the latter entities are specified in Clause 20. Figure 19-2 shows that the two enclosing SAPs are not equivalent. The upper SAP in the figure is the Passive SAP. It lies closer to the DoSAP of the monitored service instance. The lower SAP in the figure is the Active SAP, the one that faces the monitored service instance. Thus, Figure 19-2 illustrates one of the Down MEPs shown in Figure 22-1. To illustrate one of the Up MEPs of Figure 22-1, Figure 19-2 would have to be inverted. Note also in the diagram that there are two paths, one of which is present only in the Up MEP, and one of which is present only in the Down MEP.

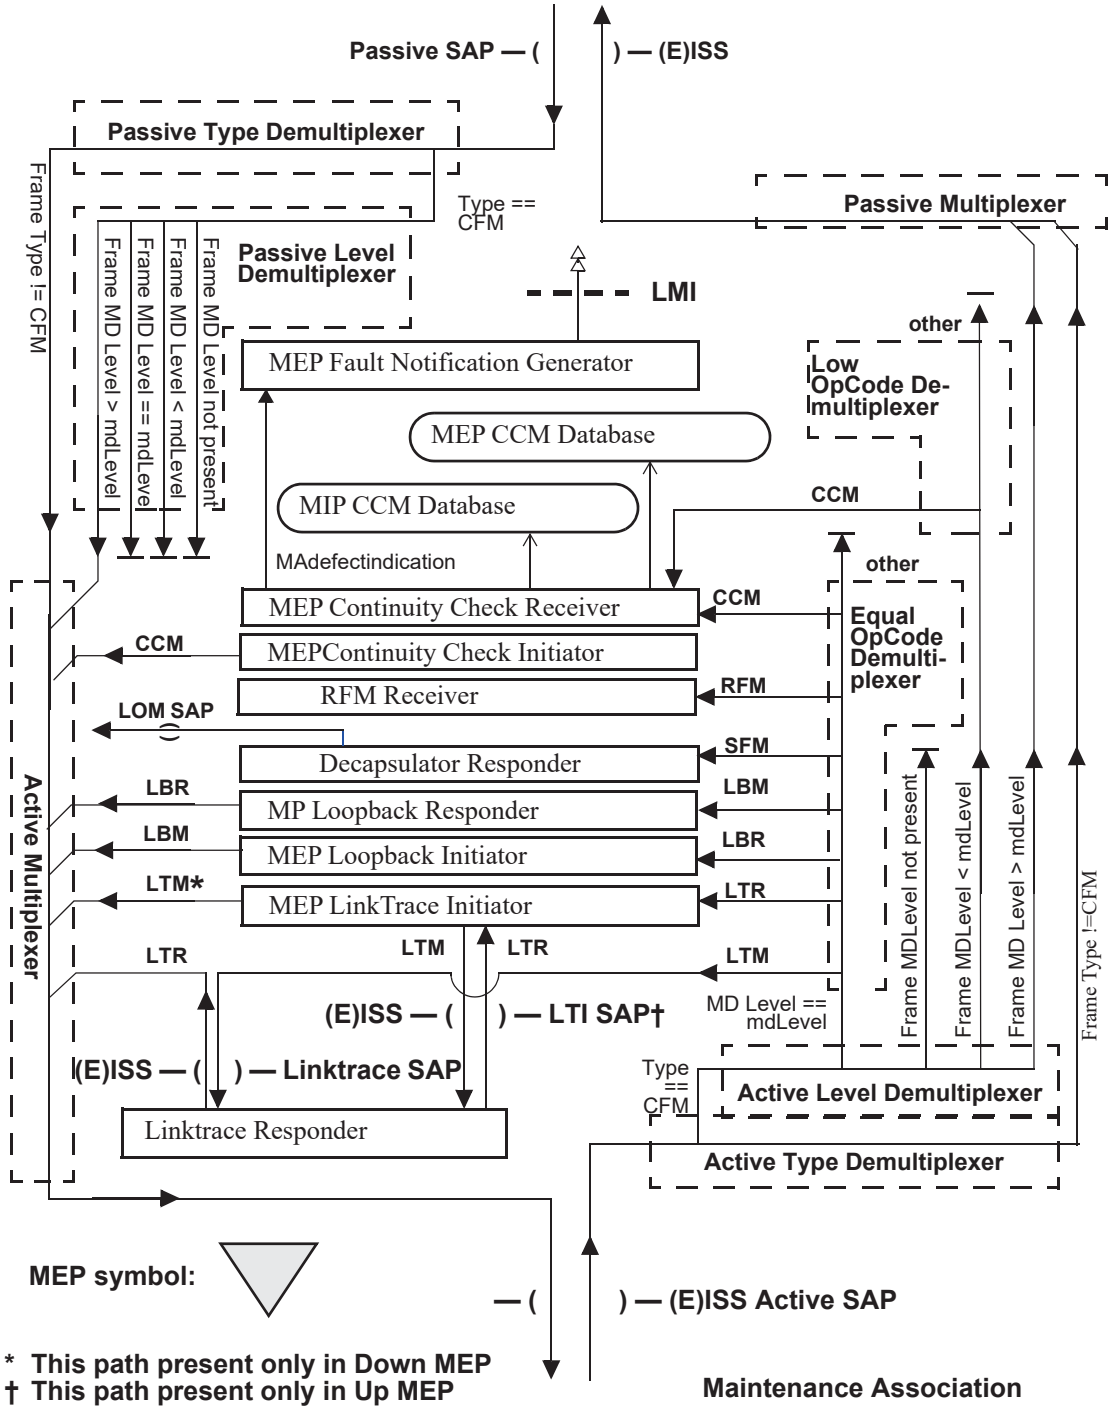

Figure 19-2—MA Endpoint (MEP)

19.2.4 MP Type Demultiplexer

There are two MP Type Demultiplexers in a MEP, the Active and the Passive Type Demultiplexers, and one in an MHF. All have the same purpose: to separate the data frames from those carrying CFM PDUs using the CFM encapsulation (21.2), output non-CFM frames to one output, and output the CFM frames to a second output. Frames containing CFM PDUs are sent to the Level Demultiplexer, and non-CFM frames are passed through the MEP intact.

NOTE—The model used for functional entities in this standard assumes that the operations of the components shown in Figure 19-2 and Figure 19-3 are atomic with respect to each other, so that the demultiplexing and multiplexing of frames, e.g., of CFM and non-CFM frames, cannot change the order of delivery of these frames. Although such reordering has no adverse consequences on this standard, and although it would not normally violate the frame ordering requirements of 6.5.3 (because CFM and non-CFM frames would seldom have the same source and destination MAC address pairs), this reordering could cause the frame loss measurement operations of ITU-T G.8013/Y.1731 to fail to operate correctly. IEEE Std 802.1AX also can disrupt the operation of ITU-T G.8013/Y.1731 frame loss measurement operations.

19.2.5 MP Multiplexer

There are two MP Multiplexers in a MEP or in an MHF, the Active and the Passive Multiplexers. An MP Multiplexer merges frames from multiple inputs and outputs them to a single output. No frame queuing is specified or implied by this standard.

19.2.6 MP Level Demultiplexer

There are two MP Level Demultiplexers in a MEP, the Active and Passive Level Demultiplexers. Both separate CFM PDUs according to the MD Level contained within the PDU, and the MD Level configured in the MEP, and output them to different outputs. Specifically,

a) Any CFM PDU received that is too short to contain an MD Level header field shall be discarded.

b) Otherwise, the MD Level header field of the CFM PDU is compared to the MD Level configured for the MP [item b) in 12.14.5.1.3, item b) in 12.14.3.2.2, 20.7.1], and the CFM PDU is directed to one of the three outputs of the MP Level Demultiplexer, according to whether the CFM PDU's MD Level is less than, equal to, or greater than the MP's MD Level.

19.2.7 MP OpCode Demultiplexer

There are two MP OpCode Demultiplexers in a MEP, the Equal and the Low OpCode Demultiplexers, and one in an MHF. Each MP OpCode Demultiplexer separates CFM PDUs that carry different values in their OpCode fields (see 21.4.3), and either discards them or passes them to the appropriate state machine. Those PDUs that do not match any of the OpCodes recognized by an MP OpCode Demultiplexer, or that are too short to contain an OpCode, are discarded by either of a MEP's MP OpCode Demultiplexers, and passed to the Passive MHF Multiplexer by an MHF's MP OpCode Demultiplexer. Those PDUs that do match a recognized OpCode are stored in a variable and cause another Boolean variable to be set, according to Table 19-1. These variables, in turn, trigger state machine actions. The three MP OpCode Demultiplexers separate different sets of OpCodes; see Figure 19-2 (in 19.2.3) and Figure 19-3 (in 19.3.3).

19.2.8 MEP Continuity Check Receiver

The MEP Continuity Check Receiver receives CCMs whose MD Levels are equal to or less than the MD Level of the MEP. The MEP Continuity Check Receiver processes those at or lower than its own MD Level, to update the MEP CCM Database. The MEP Continuity Check Receiver maintains one instance of the Remote MEP state machine (20.20) for each active remote MEP configured for this MA. In addition, the MEP Continuity Check Receiver maintains a single instance each of the Remote MEP Error state machine (20.22) and the MEP Cross Connect state machine (20.24).

Table 19-1—Actions taken by MP OpCode Demultiplexers

OpCode	MEP Equal OpCode Demultiplexer	MEP Low OpCode Demultiplexer	MHF OpCode Demultiplexer
CCM	Sets CCMreceivedEqual and CCMequalPDU for 20.18	Sets CCMreceivedLow and CCMlowPDU for 20.18	Sets MHFrecvdCCM and MHFCCMPDU for 20.15 and transfers CCM to Passive MHF Multiplexer
LBM	Sets LBMreceived and LBMPDU for 20.29	Discards PDU	Sets LBMreceived and LBMPDU for 20.29 and in non-PBB-TE MHFs transfers LBM to Passive MHF Multiplexer
LBR	Sets LBRreceived and LBRPDU for 20.34	Discards PDU	Transfers LBR to Passive MHF Multiplexer
LTM	Transfers LTM to MEP Linktrace SAP	Discards PDU	Transfers LTM to MHF Linktrace SAP
LTR	Sets LTRreceived and LTRPDU for 20.45	Discards PDU	Transfers LTR to Passive MHF Multiplexer
Other	Discards PDU	Discards PDU	Transfers PDU to Passive MHF Multiplexer
SFM	Sets SFMreceived (29.3.8.5) and SFMPDU (29.3.8.3)	Discards PDU	Sets SFMreceived (29.3.8.5) and SFMPDU (29.3.8.3). Transfers the SFM to Passive MHF Multiplexer
RFM	Sets RFMreceived (29.3.6.1) and RFMPDU (29.3.6.2)	Discards PDU	Sets RFMreceived (29.3.6.1) and RFMPDU (29.3.6.2). Transfers the RFM to Passive MHF Multiplexer

If a MEP's Continuity Check Receiver state machine's allRMEPsDead variable (20.9.4) is set, and if the MEP is not associated with any VID or I-SID and is a Down MEP (i.e., in position 5 in Figure 22-9), then the MAC_Operational parameter presented to the Passive SAP by the MEP is false, whatever the state of the MAC_Operational parameter received from the Active SAP. Thus, a completely failed MA causes the attached Bridge Port to appear as a failed link.

Optionally, the MEP Continuity Check Receiver may maintain the MIP CCM Database as described in 19.3.10.

Various error conditions, including the receipt of CCMs at a lower MD Level than that of the MEP, cause the Remote MEP state machine to detect a defect that can in turn generate a Fault Alarm.

19.2.9 MEP Continuity Check Initiator

The Continuity Check Initiator transmits CCMs at the MD Level of the MEP only. The state machine for the Continuity Check Initiator is described in 20.12.

19.2.10 MP Loopback Responder

The Loopback Responder receives LBMs at the MD Level of the MP only, validates and filters them according to destination_address (19.4) and the PBB-TE MIP TLV (21.7.5) in the case of a PBB-TE MA and transmits LBRs in response. The state machine for the MP Loopback Responder is described in 20.29.

19.2.11 MEP Loopback Initiator

The Loopback Initiator transmits LBMs at the MD Level of the MEP only, and validates, filters according to destination_address (19.4), and counts the LBRs returned by other MPs' Loopback Responders. The state machine for the Loopback Initiator is described in 20.32.

19.2.12 MEP Linktrace Initiator

The Linktrace Initiator transmits LTMs at the MD Level of the MEP only, and validates, filters according to destination_address (19.4), and catalogs the LTRs returned by other Bridges' Linktrace Responders. The state machine for the Linktrace Initiator is described in 20.45. In an Up MEP the Linktrace Initiator transmits its LTMs to the Bridge's Linktrace Responder. In a Down MEP, the Linktrace Initiator transmits its LTMs through the MEP's own Active Multiplexer toward the MEP's Active SAP.

19.2.13 MEP LTI SAP

An Up MEP, but not a Down MEP, has a MEP LTI SAP, an instance of the ISS or EISS. This SAP is used to:

a) Transmit LTMs originated by the MEP's Linktrace Initiator.
b) Receive LTRs from the Linktrace Responder.

19.2.14 MEP Linktrace SAP

Every MEP has a MEP Linktrace SAP, an instance of the ISS or EISS. This SAP is used to relay received LTMs to the Linktrace Responder.

NOTE—Both the MEP LTI SAP and MEP Linktrace SAP are required so that the MEP knows, when an LTR is returned to it by the Linktrace Responder, whether the LTR is a response to an LTM generated by the MEP and thus to direct it to the MEP Linktrace Initiator, or whether the LTR is a response to an LTM previously received by the MEP and thus to forward it out the Active SAP.

19.2.15 MEP CCM Database

The MEP CCM Database is maintained by the Remote MEP state machines (20.20), one entry for each of the other MEPs configured in the MA. In addition to the Remote MEP variables (20.19) used by the Remote MEP state machine, each entry holds information obtained from the remote MEP's CCMs as listed in 12.14.7.6.3. See also 20.1.3.

19.2.16 MEP Fault Notification Generator

The Fault Notification Generator uses the MAdefectIndication variable (see 20.9.3) in order to generate a Fault Alarm to the administrator of the Maintenance Domain to which the MA is attached. This can be accomplished by sending an SNMP Notification. The state machine for the Fault Notification Generator is described in 20.37.

19.2.17 MEP Decapsulator Responder (DR)

The MEP DR is an optional component entity within an MEP shim required only by DDCFM. Its position relative to other MP component entities is shown in Figure 19-2. When the destination_address of the SFM matches with the MEP's MAC address, the MEP DR (29.2.6) will decapsulate the SFM, change the source_address field of the decapsulated data frame if it is required, and send the frame to the LOM SAP of selected port(s) (29.3.9.1).

19.2.18 MEP RFM Receiver

The MEP RFM Receiver is an optional component entity within a MEP shim required only by DDCFM. It is placed next to the OpCode Demultiplexer functions receiving RFM frames. When the destination_address of the RFM matches with the MP's MAC address, the MEP RFM Receiver will pass the received RFM to the corresponding, nonstandardized RFM Analyzer.

19.3 MIP Half Function

A MIP consists of two MIP Half Functions (MHFs) on a single Bridge Port, an Up MHF and a Down MHF. (See J.6 for a more detailed explanation.) An MHF may maintain a MIP CCM Database, separate from the MEP CCM Databases.

19.3.1 MHF identification

Every MHF is characterized by one configuration parameter for management purpose, and all of the MHFs of a MIP have identical values for that configuration parameter:

a) The Maintenance Domain to which the MHF is assigned.

For data flow purposes, the MHF is characterized by:

b) A Maintenance Domain Level (MD Level), inherited from its Maintenance Domain or from the Default MD Level managed object.

c) A set of Primary VIDs, one from each MA associated with the MHF's Maintenance Domain; or a set of I-SIDs, one for each MA associated with the MHF's Maintenance Domain.

NOTE—When multiple VIDs are used for a single service instance, an MHF is aware of each MA's VID set and Primary VID. Unlike the MEP, however, the MHF has no occasion to use a MAID, so is not identified by a MAID.

An MHF is associated with two Bridge Ports. For a Down MHF, both associations are with the same Bridge Port; for an Up MHF, the two associations can be with either the same, or with different, Bridge Ports (see 19.4, J.6). The two Bridge Ports are:

d) The Bridge Port on which the MHF is configured.

e) The Bridge Port on which the MHF is implemented and from which it inherits its individual MAC address.

19.3.2 MHF functions

Each MHF:

a) Validates received LTMs as specified in 20.1, 20.2, 20.3, and 20.51.

b) Optionally, validates received CCMs and builds the MIP CCM Database.

c) Responds to LBMs with LBRs as defined in 20.2.2.

d) Responds to LTMs by forwarding them and responding with LTRs as defined in 20.3.2.

e) May decapsulate and transmit the payload of the received SFM (29.4.3).

f) May pass the received RFM (29.4.2).

Although defined as having either ISS or EISS interfaces, an MHF is highly constrained in its use of the EISS. Specifically,

g) Every frame passing through the MHF, in either direction, is emitted with its vlan_identifier and drop_eligible parameters unchanged from the value received.

h) All LBMs forwarded by the MHF carry the same vlan_identifier and drop_eligible parameters as the received LBM.

i) All PDUs generated by the MHF, namely LBRs, and LTRs, are transmitted with a vlan_identifier equal to the Primary VID of the MA to which the vlan_identifier of the received LBM or LTM belongs, or to the Reverse VID field of the PBB-TE MIP TLV if the received LBM or LTM carries such a TLV.

19.3.3 MHF architecture

Figure 19-3 illustrates a single MHF. Entities that simply pass, redirect, or filter frames without altering them, and that have no internal state, are shown with dashed outlines; those that generate or transform frames, or that have an internal state, are shown with continuous outlines. State machines describing the latter entities are specified in Clause 20. Figure 19-3 shows that the two enclosing SAPs are not equivalent. The upper SAP in the figure is the Passive SAP. This lies nearer an ISAP for the monitored service instance. The lower SAP in the figure is the Active SAP, the one through which CFM PDUs are actively transmitted and received. Thus, Figure 19-3 illustrates one of the Down MHFs shown in Figure 22-1. To illustrate one of the Up MHFs of Figure 22-1, Figure 19-3 would have to be inverted.

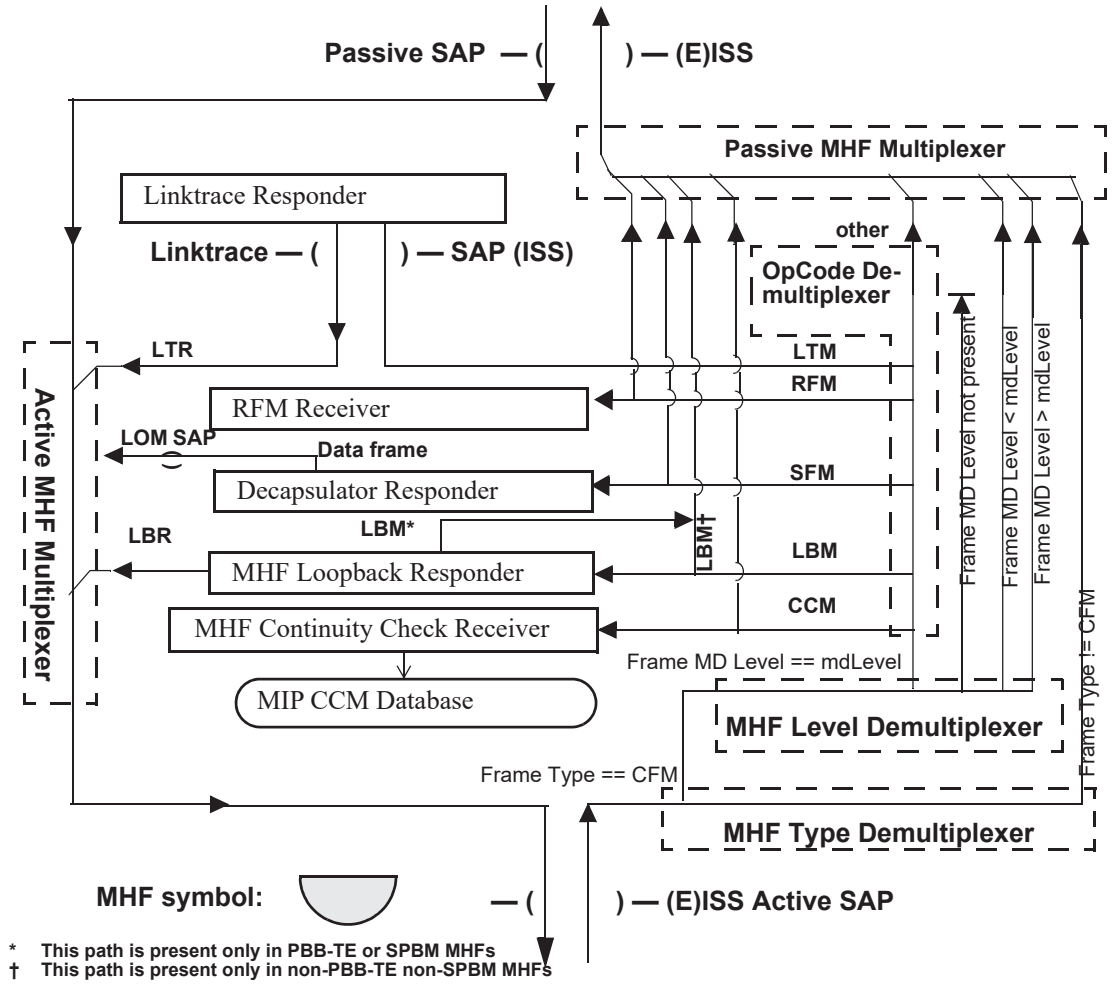

Figure 19-3—MIP Half Function (MHF)

19.3.4 MHF Level Demultiplexer

The MHF Level Demultiplexer is identical to the MP Level Demultiplexer described in 19.2.6.

19.3.5 MHF Type Demultiplexer

The MHF Type Demultiplexer is identical to the MP Type Demultiplexer described in 19.2.4.

19.3.6 MHF OpCode Demultiplexer

An example of the MP OpCode Demultiplexer described in 19.2.7. The MHF OpCode Demultiplexer is fully described in that subclause.

NOTE—As indicated by the split arrows labeled “CCM” and “LBM” in Figure 19-3, some of the frames output from the MHF OpCode Demultiplexer are supplied to two other entities, and not just one.

19.3.7 MHF Multiplexer

The MHF Multiplexer is identical to the MP Multiplexer described in 19.2.5. There are two MHF Multiplexers in an MHF, the Active MHF Multiplexer and the Passive MHF Multiplexer.

19.3.8 MHF Loopback Responder

The MHF Loopback Responder is identical to the MP Loopback Responder described in 19.2.10.

19.3.9 MHF Continuity Check Receiver

The optional MHF Continuity Check Receiver receives CCMs, validates them, filters them by destination_address parameter (19.4), and contributes to the MIP CCM Database. From Figure 19-3, readers can see that all CCMs at the same MD Level as the MHF are presented to the MHF Continuity Check Receiver. No other information in the received CCMs is examined. In particular, the MAID in the CCM is not compared to the MHF’s MAID.

The MHF Continuity Check Receiver, and the MIP CCM Database it maintains, are not required for conformance to this standard.

19.3.10 MIP CCM Database

The MIP CCM Database is optionally maintained by an MHF or MEP. It is a list of every distinct {FID, source_address, Port number} triple from all of the CCMs presented to all of the Bridge’s MPs’ Continuity Check Receivers since the Bridge was last reset. Entries in the MIP CCM Database are timed out very slowly, on the order of one day, so that their information is available for fault isolation long after the information is no longer used for frame forwarding.

19.3.11 MHF Linktrace SAP

Every MHF has an MHF Linktrace SAP, an instance of the ISS or EISS. This SAP is used to relay received LTMs to the Linktrace Responder, and to pass LTRs from Linktrace Responder to the MHF’s Active SAP.

19.3.12 MHF DR

The MHF DR is identical to the MEP DR described in 19.2.17.

19.3.13 MHF RFM Receiver

The MHF RFM Receiver is identical to the MEP RFM Receiver described in 19.2.18.

19.4 MP addressing

The CFM entities within an MP use the Group addresses for CCM and LTM PDUs listed in Table 8-18 and Table 8-19 and in the case of PBB-TE, SPBM, and ECMP path MAs, the individual MAC addresses or the group MAC addresses that are associated with the monitored services (20.1, 20.2, 20.3). In addition, they recognize and in the case of PBB-TE, SPBM, and ECMP path MEPs use the individual MAC address of the port on which the MP is operating. This is the port on which the MP is configured, if the Bridge created the MP using the Individual MP address model (J.6.1), and is a CFM Port, if the Bridge created the MP using the Shared MP address model (J.6.2). CFM entities associated with a TESI may also use the ESP-SA parameter in the tuple identifying the corresponding ESP.

A Down MP shall not be assigned an individual MAC address [item i) in 12.14.7.1.3] that is the same as the individual MAC address configured for an MP on any other Bridge Port, because if two Bridge Ports are connected to the same LAN, but have the same MAC address, then both would respond to an LBM sent to that MAC address. The CFM protocol is specifically designed to allow an Up MP to be assigned an individual MAC address that is the same as the individual MAC address configured for an Up MP on some other Bridge Port, because it is impossible to tell, from outside the Bridge, from which Up MP a given CFM PDU was actually transmitted, or to which physical entity a given CFM PDU was delivered. See J.6 for a discussion of the assignment of individual MAC addresses to MPs.

All the CFM entities within one MP use the same CCM and LTM addresses, and individual MAC address. The various multiplexing and demultiplexing entities pay no attention to the destination_address parameter of a received CFM PDU. Only the entities responsible for processing received CFM PDUs check a received frame's destination_address parameter. Each of these entities recognizes frames whose destination_address parameters match the individual MAC address of the MP or are a group address. Each of these entities (except the MEP Continuity Check Receiver) filters and does not process frames whose destination_address parameters are not a group address and do not match the individual MAC address of the MP.

NOTE—Even though in the original version of IEEE Std 802.1ag-2007, the MEP Continuity Check Initiator could only transmit multicast CCMs, the MEP Continuity Check Receiver recognized unicast CCMs. In general the definitions of the various CFM receiving entities were more liberal in recognizing certain Individual or group MAC addresses than the corresponding definitions of the CFM transmitting entities a property that allows for the PBB-TE enhancements of CFM, and for improved compatibility with ITU-T G.8013/Y.1731.

19.5 Linktrace Output Multiplexer (LOM)

The third type of CFM protocol shim is the LOM. An LOM has two principle SAPs, an Active SAP, through which CFM PDUs are transmitted, and a Passive SAP, through which pass data frames and unprocessed CFM PDUs. Figure 19-4 illustrates these SAPs and the symbol used for the LOM in other figures, e.g., Figure 22-1. An LOM can be only a Down LOM; its Passive SAP is always above the Active SAP in a shim diagram.

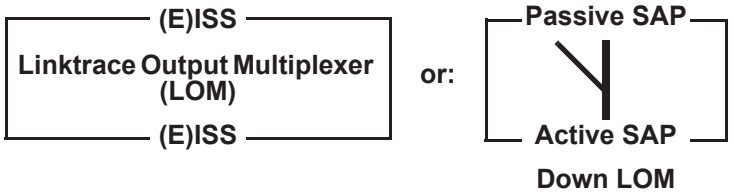

Figure 19-4—LOM shim

As illustrated in Figure 19-5, the LOM has only a single active entity, the LOM Multiplexer. It injects LTMs from the Linktrace Responder among the frames passing from the LOM's Passive SAP to its Active SAP. Frames received from the LOM's Linktrace SAP are transmitted through only the Active SAP, and not

through the Passive SAP. All frames received on either the Active or Passive SAP are passed through the LOM unchanged, and only to the Passive or Active SAP, respectively.

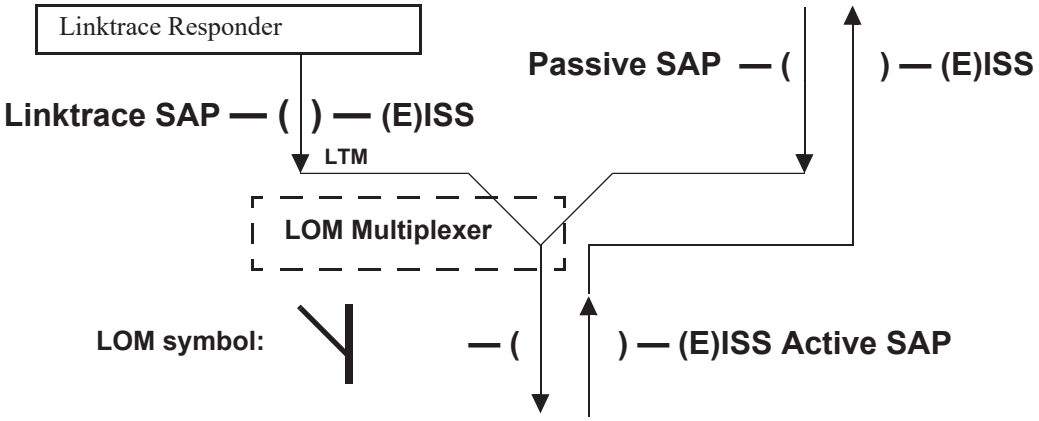

Figure 19-5—LOM architecture

NOTE 1—An LOM is not an MP, but an entity that assists the Linktrace Responder (19.6), also not an MP.

NOTE 2—The LOM exists on every Bridge Port in order to allow the Linktrace Responder to transmit an LTM on a particular Bridge Port without the possibility of that LTM being reflected back toward the Bridge's Forwarding process. However, the LOM has no constituent entity that differentiates CFM frames from any other frames.

19.6 Linktrace Responder

A single Linktrace Responder serves all of the MHFs and MEPs in a Bridge. It is connected to every MP and LOM in the Bridge, via the Linktrace SAPs and LTI SAPs in those MPs and LOMs.

NOTE—A Linktrace Responder is not an MP, but an entity that assists the MPs (MEP and MHF, 19.2 and 19.3) in performing their functions.

In order to minimize the possibility of generating an unbounded number of responses to an LTM, an LTM is always transmitted from a Bridge on a single Bridge Port (20.3). If the LLC entity of a Bridge Port (see Figure 22-1) were used to transmit an LTM on a particular Bridge Port, the Bridge Port connectivity entity (8.5.1) would direct the LTM to the LAN, but it would also pass that frame up toward the Frame filtering entity (8.6.3), as it does for BPDUs. BPDUs are never transmitted to other Bridge Ports, however, because the Frame filtering entity filters them, based on their destination MAC addresses. The placement of MHFs at different MD Levels on different Bridge Ports, all for the same VID, precludes filtering LTMs in this manner. Therefore, the Linktrace Responder filters incoming LTMs by the destination_address parameter (19.4), and a path is required that will direct an LTM only down the Bridge Port, toward the LAN, and not toward the Frame filtering entity.

This path is provided by the Linktrace SAPs in the MEP (Figure 19-2), the MHF (Figure 19-3), and the LOM (Figure 19-5). The Linktrace SAPs are also used to direct a received LTM to the Linktrace Responder when the LTM first encounters an MP at the appropriate MD Level.

Referring to Figure 22-1, readers can see that an LTM originated by a Down MEP Linktrace Initiator is directed out to the LAN and is thus output on a single Bridge Port, as desired. The situation is different for an LTM originated by an Up MEP. The Bridge in which an Up MEP resides is, in effect, the first hop of the Linktrace protocol. The MEP LTI SAP is required in order to provide a path through which the MEP can direct its originated LTM to the Linktrace Responder. This path can also be used by the Linktrace Responder to return the resultant LTR to the MEP Linktrace Initiator. See Figure 20-16 for a diagrammatic explanation of these paths.

Table 19-2 summarizes the SAP connections between the MPs and LOM on the one hand, and the Linktrace Responder, on the other.

Table 19-2—SAP use for LTMs and LTRs

Entity taking action		Sends originated LTM to	Relays received LTM to	Sends to Active SAP an LTR received on	Sends to Active SAP an LTM received on
Up	MEP	MEP LTI SAP	MEP Linktrace SAP	MEP Linktrace SAP	Not applicable [a]
	MHF	Not applicable [b]	MHF Linktrace SAP	MHF Linktrace SAP	Not applicable [a]
Down	MEP	Not applicable [c]	MEP Linktrace SAP	MEP Linktrace SAP	Not applicable [a]
	MHF	Not applicable [b]	MHF Linktrace SAP	MHF Linktrace SAP	Not applicable
LOM		Not applicable [b]	Not applicable [d]	Not applicable [a]	LOM Linktrace SAP

[a] The Linktrace Responder only forwards LTMs through an LOM.
[b] The MHF and LOM have no MEP Linktrace Initiator, so cannot originate LTMs.
[c] The Down MEP transmits the LTMs it originates through its Active SAP.
[d] The LOM is not an MP; it cannot detect received LTMs.

A single instance of the LTR Transmitter state machine is instantiated by the Linktrace Responder. It is described in 20.50.

20. CFM protocols

MEPs and MIPs can participate in the following CFM protocols:

a) Continuity Check protocol (20.1)
b) Loopback protocol (20.2)
c) Linktrace protocol (20.3)
d) DDCFM protocol (29.3)

The detailed operation of these protocols by the MEP (19.2) and MHF (19.3) components introduced in Clause 19 is specified in terms of a number of state machines, and the variables and procedures associated with each machine. The state machines defined adhere to the conventions in Annex E and Figure 13-14.

This clause specifies the following:

e) Relationships among the various CFM state machines and their variables (20.4).
f) Requirements for decrementing the timer counters used by a number of CFM state machines (20.5).
g) Maintenance Domain variables (20.7) that control all MAs belonging to the Maintenance Domain.
h) MA variables (20.8) that control all MEPs and MHFs belonging to the MA.
i) MEP variables (20.9) that control the MEP's overall operation, and either apply to the majority of state machines or facilitate communication of information between the individual MEP state machines.
j) MEP Continuity Check Initiator (19.2.9) variables (20.10), procedures (20.11), and state machine (20.12).
k) (optional) MHF Continuity Check Receiver (19.3.9) variables (20.13), procedures (20.14), and state machine (20.15).
l) MEP Continuity Check Receiver (19.2.8) variables (20.16), procedures (20.17), and state machine (20.18).
m) Remote MEP variables (20.19) and state machines (20.20) used by the MEP Continuity Check Receiver to track each active Remote MEP [item ae) in 12.14.7.1.3].
n) Remote MEP Error variables (20.21) and the Remote MEP Error state machine (20.22) used by MEP Continuity Check Receiver to track received invalid CCMs.
o) MEP Cross Connect variables (20.23) and state machine (20.24) used by the MEP Continuity Check Receiver to track received CCMs that could indicate a cross connect defect.
p) MP Loopback Responder (19.2.10) variables, (20.27), procedures (20.28), and state machine (20.29).
q) MEP Loopback Initiator (19.2.11) variables (20.30), transmit procedures (20.31) and state machine (20.32), and receive procedures (20.33) and state machine (20.34).
r) MEP Fault Notification Generator (19.2.16) variables (20.35), procedures (20.36), and state machine (20.37).
s) MEP Linktrace Initiator (19.2.12) variables (20.41) and transmit procedures (20.42), and receive variables (20.43), procedures (20.44), and state machine (20.45).
t) Linktrace Responder variables (20.46), procedures (20.47), and state machine (20.48), used by the Linktrace Responder (19.6).
u) LTR Transmitter state machine (20.50) used only by the Linktrace Responder.

To facilitate extension of this standard while maximizing interoperability, this clause further specifies:

v) Rules for CFM PDU validation and versioning (20.51) that support specific goals for extensibility and interoperability (20.51.1).
w) Rules for the identification of incoming CFM PDUs (20.52).
x) Rules for the use of transaction identifier and sequence number fields (20.53).

The models of operation in this clause provide a basis for specifying the externally observable behavior of MHFs and MIPs, and are not intended to place additional constraints on implementations; these can adopt any internal model of operation compatible with the externally observable behavior specified. Conformance of equipment to this standard is purely in respect of observable protocol.

NOTE—Clause 18 introduces the principles of CFM operation and the network architectural concepts that support it. Clause 19 breaks down the CFM protocol entities into their components. Clause 21 specifies the PDU formats used by the CFM protocols. The use of CFM within systems and networks is further described in Clause 22.

20.1 Continuity Check protocol

The Continuity Check protocol is performed by the MEP Continuity Check Initiator (19.2.9), the MEP Continuity Check Receiver (19.2.8) of the MEP, and optionally, in the MHF Continuity Check Receiver (19.3.9) of the MHF.

For the purposes of Fault detection and the Continuity Check protocol, readers can define an MA as "a set of MEPs, all of which are configured with the same MAID and MD Level, each of which is configured with a MEPID unique within that MAID and MD Level, and all of which are configured with the complete list of MEPIDs." The CCM (21.6) provides a means to detect connectivity failures in an MA. Each MEP can be configured to periodically transmit a CCM. A connectivity failure is then defined as one of the following:

a) Inability of a MEP to receive three consecutive CCMs from any one of the other MEPs in its MA, indicating either a MEP failure or a network failure.
b) Reception by a MEP of a CCM with an incorrect transmission interval, indicating a configuration error.
c) Reception by a MEP of a CCM with an incorrect MEPID or MAID, indicating a configuration error or a cross connect error.
d) Reception by a MEP of a CCM with an MD Level lower than that of the MEP, indicating a configuration error or a cross connect error.
e) Reception by a MEP of a CCM containing a Port Status TLV or Interface Status TLV indicating a failed Bridge Port or aggregated port.
f) Reception by a PBB-TE MEP implementing the Traffic field, over a period of time that is 4.75 times the CCM interval or equal to 50 ms, whichever is larger, of CCMs with Traffic fields not matching the local Traffic field declaration, indicating a mismatch on the presence or absence of Backbone Service Instance entries on the CBPs that are associated with the monitored TESI.

In order to take the fullest advantage of CFM, the operator defines "correct connectivity" as being the configuration of the MEPs. If an MA is defined for every service instance, then the Continuity Check protocol can detect 100% of all connectivity faults, cross connection errors, or misconfigurations that occur within the boundaries of the configured MAs.

The transmission rate for CCMs is configurable, to accommodate different needs for error reporting, and different capabilities of network devices. The loss of three CCMs can be detected in as little as 10.8 ms (see Table 21-15). The reception of a cross connected CCM is an instantaneous occurrence.

A MEP uses its own configured timer to detect the loss of CCMs, rather than using the transmission rate of the sender (signaled in the CCM), in order to minimize the complexity of a MEP tracking hundreds of other MEPs. The timer is reset when a valid CCM is received, and a defect declared if the timer expires. The timer value is chosen such that the loss of three consecutive CCMs from a given remote MEP triggers a defect for that remote MEP, and the timer accuracy chosen to ensure against a premature defect indication. In addition, state machines in the MEP track the receipt of CCMs from remote MEPs with unexpected information, CCMs from remote MEPs not configured in the receiving MEP, CFM PDUs from a lower MD Level, or CCMs from MEPs in another MA.

Depending on the associated MA, a CCM is carried:

g) In a multicast frame, with a destination_address parameter chosen according to the transmitting MEP's MD Level, according to Table 8-18; or

h) In the case of a PBB-TE, SPBM, or ECMP associated MA, in a unicast or multicast frame with a destination_address identified by the monitored MA.

The CCM does not generate a response. Therefore, in an MA with *n* MEPs, *n* CCMs need to be transmitted periodically, one from each MEP. Compared to a full mesh of point-to-point messages in terms of frames carried on wires, multicast CCMs require less bandwidth than the point-to-point messages, except of course for MAs with only two MEPs. And for each MEP, only one transmission and $n - 1$ receptions are required, instead of $n - 1$ of each. In addition, even in MAs with only two MEPs, using multicast instead of unicasts for CCMs obviates the need for configuration or discovery of those MEPs' MAC addresses.

Of more importance than frame count is the fact that making the CCM a multicast frame enables the detection of a cross connect error when MEPs from two different service instances are accidentally connected. This type of error can result from a wiring error or a misconfiguration of VID mapping parameters at the boundary between two Maintenance Domains. Were CCMs unicast to specific MAC addresses, then a merging of two service instances, e.g., the accidental concatenation of two point-to-point services into a 4-SAP LAN service, would go undetected; unicast CCMs would still be delivered properly. This scenario also points out why globally unique MAIDs are important.

NOTE—The TESI Multiplex Entity (6.19) helps PBB-TE associated MEPs to avoid this type of cross connect problem for unicast CCMs by checking the source_address to determine CCMs destined to PBB-TE MAs. Correspondingly the assignment of globally unique MAIDs is not as important for PBB-TE MAs as it is for other types of MAs but in general a globally unique MAID will provide guaranties for full coverage on all possible misconfiguration errors.

Cataloging the receipt of CCMs ensures that a MEP, say, MEP 1, knows that it is receiving them from exactly the correct set of remote MEPs; it does not ensure that the CCMs transmitted by that same MEP are being received by the remote MEPs. For example, suppose that in a 10-MEP MA, all of MEP 1's CCMs are being lost. All of the other MEPs in the MA would know about MEP 1's problem, because they would not be receiving 1's CCMs. But, MEP 1 itself would be unaware of the problem. In order for the operator to decide whether an MA is working properly, every MEP in the MA would have to be inspected.

For this reason, the Remote Defect Indication (RDI), a single bit, is carried by the CCM. The absence of RDI in a CCM indicates that the transmitting MEP is receiving CCMs from all configured MEPs. In the case of MEP 1's unidirectional connectivity, MEP 1 would receive the RDI in the CCM from each remote MEP that is not receiving MEP 1's (or any other MEP's) CCMs. Thus, every MEP, including the receive-only MEP 1, is aware that a problem exists. The presence of RDI enables a system administrator to inspect any single MEP belonging to an MA, and discover whether there is any MEP in the MA that is detecting a defect, as well as which particular MEPs have defects.

A sequence number should be transmitted in every CCM. The receiver may use this sequence number to detect and count CCM losses. Detection of occasional CCM losses can enable a network administrator to notice suboptimal network conditions such as overloaded links, and correct them before connectivity defects and their consequent Fault Alarms occur.

An ECMP path MA is used to test multiple paths between a pair of endpoints. This type of MA has only two MEPs, at two SPT Region boundary ports. An ECMP path MEP cycles through a set of flow hash values intended to direct the CCM frames along (and thus test) different paths to the other MEP in the MA. The path taken by CCM frames with a given flow hash depends on the current state of the network (i.e., paths are subject to rerouting triggered by topology changes). Each flow hash is used in at least three consecutive CCM frames so that a fault on a particular path will be detected and reported back via an RDI signal. To avoid false positive or false negative detections of a loss of connectivity, the rate of CCM transmission should be greater than the maximum difference in latency between any pair of paths.

20.1.1 MAC status reporting in the CCM

The CCM can carry information about the status of the port on which the transmitting MEP is configured in the Port Status TLV (21.5.4) and Interface Status TLV (21.5.5). This information is not strictly within the scope of the MA bounded by the MEPs transmitting and receiving the CCM. But, by providing port status information in an Up MEP's CCMs, this TLV allows the detection of an error immediately outboard of the MA. This in turn supports fault isolation where a problem has arisen at the point of connection to a service instance, rather than within the equipment supporting the service instance. The Port Status TLV and Interface Status TLV are particularly useful where the boundary between the equipment used by two operators to support a service instance is a link or connection that could fail. Use of the Port Status TLV and Interface Status TLV allows monitoring to be uninterrupted from end to end, without requiring management access by both operators to a single item of interface equipment, or relying on monitoring by the user of the concatenated service. The Port Status TLV and Interface Status TLV allow errors that are immediately outboard of the MA to be distinguished easily from those properly attributed to the MA itself.

Figure 18-7 provides an example. Consider a failure of the access link that connects the customer equipment (1) directly to Port b of Provider Bridge 2. Without the Interface Status TLV, none of the MEPs at the operator or service provider MD Level would be notified of the error. The Interface Status TLV allows the failure to be signaled in CCMs transmitted by the Port b service provider and operator MD Level MEPs.

20.1.2 Defects and Fault Alarms

Defects are separated from Fault Alarms (19.2.16), as is standard practice for service providers.[34] The loss of CCMs or the reception of a cross connected CCM is a defect. A Fault Alarm is a Management operation (12.14.7.7), an unsolicited announcement by a Bridge. If the CFM MIB module (17.5) is implemented and is operating, an SNMP Notification is sent. If the CFM YANG module (Clause 48) is implemented and is operating, a YANG Notification is sent. Notifications are sent when the MEP Fault Notification Generator state machine (20.37), or the MEP Mismatch Fault Notification Generator state machine (20.40), detects that a configured time period (default, 2.5 s) has passed with one or more defects indicated, and Fault Alarms are enabled. Each of these state machine can transmit no further Fault Alarms until it is reset by the passage of a configured time period (default, 10 s) during which no defect indication is present. The normal operator procedure upon receiving a Fault Alarm is to inspect the reporting MEP's managed objects, diagnose the fault, correct the fault, examine the MEP's managed objects to see whether the state machine has reset, and repeat those steps until the Fault Alarm has cleared.

A number of separate defects are maintained by a MEP, as shown in Table 20-1. The defects are ranked by priority. If a higher priority defect occurs after a lower priority defect has triggered a Fault Alarm, but before the Fault Alarm has reset, then the MEP will immediately issue another Fault Alarm. This enables the operator to reliably prioritize Fault Alarms. For example, cross connect errors are typically of greater concern in a service provider environment than loss of connectivity errors.

Only the highest priority defect is reported in the Fault Alarm. Table 20-1 shows the relationships between the variables that indicate defects, the priorities of these defects, and the enumerated value reported in the Fault Alarm for each defect. The mmdefectIndication (20.38.2) is independent from the other CFM defects and is reported independently by the operation of the MEP Mismatch Fault Notification Generator state machine (20.40).

20.1.3 CCM reception

Every active MEP receives and catalogs CCMs in its MEP CCM Database. Every CCM shall be examined to be sure that its MAID matches that configured in the receiving MP. This check is optional for CCMs associated with PBB-TE MAs. A receiving MEP checks to ensure that its own MEPID does *not* match that

[34] See, for example, ITU-T G.806 (2006) [B47].

Table 20-1—Fault Alarm defects and priorities

Defect		Priority	
Variable	**highestDefect (20.35.9)**	**highestDefectPri (20.35.8)**	**Importance**
xconCCMdefect (20.23.3)	DefXconCCM	5	Most
errorCCMdefect (20.21.3)	DefErrorCCM	4	
someRMEPCCMdefect (20.35.5)	DefRemoteCCM	3	
someMACstatusDefect (20.35.6)	DefMACstatus	2	
someRDIdefect (20.35.7)	DefRDICCM	1	Least

in the received CCM. (This could indicate either a duplicate MEPID or a network forwarding loop.) The information in the CCM is cataloged in the MEP CCM Database, indexed by the received MEPID. The information kept in the MEP CCM Database is listed in 12.14.7.6.3.

The MIP CCM Database is optionally maintained by a MEP Continuity Check Receiver or an MHF Continuity Check Receiver. It is a list of every distinct {FID, source_address, Port number} triple from all of the CCMs presented to all of the Bridge's Down MHFs' MHF Continuity Check Receivers since the Bridge was last reset. (See 8.8.8 for a discussion of VIDs and FIDs.) An entry in the CCM Database is retained for at least 24 h after the last CCM with its triple is received and is removed from the MIP CCM Database after, at most, 48 h. If the resources allocated for the MIP CCM Database are not sufficient to maintain all of the entries for the required time, then the least-recently updated entries should preferentially be removed to make room for new entries. See 20.3.2 for a description of the use of the MIP CCM Database.

20.2 Loopback protocol

The Loopback protocol is used for Fault verification and isolation. To verify the connectivity between MEPs and MIPs, a MEP can be instructed by a system administrator to issue one or more LBMs. The LBM is initiated by a MEP with specified destination_address, priority, and drop_eligible parameters, the destination_address being the individual MAC address of another MP within the same MA as the transmitting MEP. In the case of PBB-TE and SPBM VID MAs, the destination_address parameter for an LBM is always a MAC address associated with the terminating CBP(s). In order to identify intermediate MHFs in PBB-TE and SPBM VID MAs, an additional TLV, the PBB-TE MIP TLV (21.7.5), is carried as the first TLV in an LBM, with the receiving MHF's MAC address in its MIP MAC address field (21.7.5.1). The receiving MP responds to the LBM with an LBR.

The Loopback protocol is performed by the MEP Loopback Initiator (19.2.11) and the MP Loopback Responder (19.2.10), the latter residing in either a MEP or an MHF.

20.2.1 LBM transmission

LBMs are transmitted by operator command as specified in 12.14.7.3. Each LBM transmitted contains a Loopback Transaction Identifier field (21.7.3) that is incremented with each transmission. That enables the transmitting MEP to correlate the returned LBRs with the transmitted LBMs. In a PBB-TE or SPBM VID

MA, a PBB-TE MIP TLV is carried by the transmitted LBM as the first TLV if the targeted MP is a MIP. The MIP MAC address field (21.7.5.1) in the TLV is set to the destination_address parameter of the appropriate managed object [item b) in 12.14.7.3.2]. The PBB-TE MIP TLV provides also the Reverse VID field [21.7.5.2, item f) in 12.14.7.3.2] to be used in the VID field by a MIP transmitted LBR, and, when the LBM is to be sent on a point-to-multipoint TESI, the Reverse MAC field (21.7.5.3) associated with MAC addresses to be used by the LBR. The LBM can carry an arbitrary amount of data to help diagnose faults that are sensitive to the amount or pattern of data in a frame [item d) in 12.14.7.3.2]. It can be sent with any priority or drop_eligible parameters [item e) in 12.14.7.3.2].

No means for specifying the rate at which the LBMs are to be sent is provided. A Bridge shall not transmit LBMs at a rate that would cause the queues serving that Bridge Port to overflow and drop LBMs, were there no other traffic being inserted into those queues.

20.2.2 LBM reception and LBR transmission

When an LBM is received by an MP Loopback Responder (19.2.10), it may be examined for validity and discarded if invalid. Regardless of whether the LBM is examined for validity, it shall be discarded if the source_address is a Group and not an individual MAC address. Also, if the destination_address does not match the MAC address of the receiving MP, and the MP Loopback Responder does not reside in a PBB-TE or SPBM VID MHF, the MP shall discard the LBM. If the receiving MP Loopback Responder resides in a non-PBB-TE and non-SPBM VID associated MHF and the destination_address is a group MAC address, the MHF shall discard the LBM. If the MP Loopback Responder state machine resides in a PBB-TE MEP and the received LBM carries a PBB-TE MIP TLV, the MEP shall discard the LBM. If the MP Loopback Responder state machine resides in an SPBM VID MEP and the received LBM carries a PBB-TE MIP TLV, the MEP may process the LBM if the MIP MAC address field matches the MEP's address and shall otherwise discard the LBM. PBB-TE and SPBM VID MHFs forward all received LBMs and only stop and process those that carry a PBB-TE MIP TLV containing in their MIP MAC address field the MAC address of the receiving MIP [item f) in 20.8.1]. If the frame passes these tests, the receiving MP generates an LBR and transmits it to the originating MEP. Every M_UNITDATA.indication (or EM_UNITDATA.indication) parameter and octet in the mac_service_data_unit in the LBM is copied to the LBR's M_UNITDATA.request (or EM_UNITDATA.request) with the following exceptions:

a) The source_address parameter of the received LBM is used as the destination_address parameter for the transmitted LBR. In the case of a PBB-TE MHF, this destination_address value will be overwritten by the value of the group MAC address in the Reverse MAC field of the PBB-TE MIP TLV, if this is present. In the case of a PBB-TE MEP, the destination_address parameter for the transmitted LBR is the value of the ESP-DA of the MA's ESP that has the replying MEP's MAC address [item i) in 12.14.7.1.3] in its ESP-SA field.
b) The source_address parameter for the LBR is the MAC address of the replying MP. If the MP is associated with a PBB-TE MHF, the source_address is set to the destination_address of the received LBM if this is an individual MAC address or otherwise to the value carried in the Reverse MAC field, contained in the PBB-TE MIP TLV.
c) If the LBM was received at a PBB-TE MHF and contains a PBB-TE MIP TLV, then the vlan_identifier in the LBR is set to the value in the Reverse VID field; otherwise, the vlan_identifier in the LBR is set to the value of the Primary VID associated with the replying MP [item d) in 12.14.7.1.3, item a) in 12.14.3.2.2, item c) in 12.14.5.3.2].
d) The OpCode field is changed from LBM to LBR.
e) (Only in PBB-TE MAs) The vlan_identifier for the LBR is the Primary VID [item d) in 12.14.7.1.3] associated with the replying PBB-TE MEP; otherwise, if the received LBM contained a PBB-TE MIP TLV, the value in the Reverse VID field is used as the vlan_identifier parameter.

The receiver of an LBM shall not interpret any of the other fields or TLVs in the LBM. The contents of any TLVs that do not violate the validation criteria of 20.51, but are not specified in this standard, and any valid

Organization-Specific TLV not known to the receiving MP, shall be ignored, and not interpreted, by the receiver, except that their contents shall be copied to the LBR.

NOTE—This standard provides no means for transmitting an LBM with a group MAC address. The MP Loopback Responder responds to LBMs sent to the CCM Group address because ITU-T G.8013/Y.1731 provides for transmitting such messages. See J.4.

20.2.3 LBR reception

When an LBR is received by a MEP Loopback Initiator (19.2.11), it is checked to see whether the destination_address parameter matches the MAC address of the receiving MEP, and discarded if not. Next it is checked to see whether its Loopback Transaction Identifier field matches that of a recently transmitted LBM, and the appropriate counter incremented, either the in-sequence counter [item y) in 12.14.7.1.3] or the out-of-sequence counter [item z) in 12.14.7.1.3].

If the Shared MP address model for implementing CFM is used by a particular Bridge, then as mentioned in 20.52, there is an ambiguity in the identification of the particular Up MP to which an LBR is destined. Therefore, a Bridge using this model uses a single variable for managing the Loopback Transaction Identifier fields for all MPs sharing the same MAC address, MAID, and MD Level.

The receiver of an LBR may compare its contents bit-for-bit with the remembered contents of the corresponding LBM, and increment a variable [item aa) in 12.14.7.1.3] if they do not match.

20.3 Linktrace protocol

The Linktrace protocol is performed by the MEP Linktrace Initiator (19.2.12), associated with a single MEP, and the Linktrace Responder (19.6) associated with a Bridge.

A Linktrace Message (LTM) is transmitted by a MEP Linktrace Initiator in order to perform path discovery and fault isolation. The LTM carries a target MAC address. It is carried in a frame, with a destination_address taken from Table 8-19 according to the MD Level of the transmitting MEP, or the ESP-DA field of the appropriate ESP in the case of a PBB-TE MA (20.31.1), or an individual or group address in the case of an SPBM VID MA, and is relayed as such through the bridged network until it reaches an MP at the appropriate MD Level. That MP intercepts the LTM and deflects it to a Bridge's Linktrace Responder. The Linktrace Responder determines whether its Bridge's MAC Relay Entity would forward an ordinary data frame with the specified target MAC address and vlan_identifier to an egress Bridge Port, or would filter or flood it. If the single egress port is found, or if the receiving MP is the terminating MP, or if the MP is associated with a PBB-TE MA or an SPBM VID MA, the Linktrace Responder sends a unicast Linktrace Reply (LTR) to the originator of the LTM, whose MAC address was also carried as payload in the LTM. The LTR is sent after a random delay in the range $0 < \text{delay} \leq 1$ s, to mitigate the load on the originating MEP. In addition, if the MP through which the LTM was received was an MHF, the Linktrace Responder forwards an altered version of the LTM in the direction of the target MAC address. The MEP Linktrace Initiator that originated the initial LTM collects the LTRs. These provide sufficient information to construct the sequence of MPs that would be traversed by a data frame sent to the target MAC address.

Path discovery in a connectionless environment is more challenging than a connection-oriented environment. In Bridged Networks, it can be especially challenging, since the MAC address of the target of an LTM can be deleted from the FDB by a TCN immediately after a network topology change, and ages out and is deleted a few minutes (Max Age) after last being learned when a fault results in isolating the target from the MEP originating the LTM.

CFM offers three ways to address the problem of ageing out MAC addresses:

a) Launching the Linktrace protocol automatically, immediately following the detection of a fault, such that it gets exercised within the Max Age window.

b) Maintaining information about the destination MP at the intermediate points along the path by using the optional MIP CCM Database, 19.3.9 and 20.1.3.

c) Maintaining normal path information by issuing periodic LTMs during normal operations.

NOTE—Periodic LTMs allow a system administrator to determine the MIPs along the paths among MEPs during normal operations, thus establishing a baseline for subsequent fault isolation. However, triggering LTMs at rates approaching the CCM transmission interval could overwhelm the Bridges' ability to process CFM PDUs. See also 22.5.

20.3.1 LTM origination

LTMs are transmitted by a MEP Linktrace Initiator in response to an operator command (12.14.7.4). The nextLTMtransID [item b) in 12.14.7.4.3, 20.41.1] of each LTM transmitted is retained for at least 5 s after the LTM is transmitted. The LTM Transaction Identifier values transmitted by a given MEP are unique over this time period in order to match LTRs returned by slow MPs to the LTM that triggered the slow LTR. Initializing the nextLTMtransID to a random value[35] and incrementing it once per LTM transmitted satisfies this criterion. For each LTM transmitted, the MEP Linktrace Initiator creates an entry in a Linktrace database (20.41.2). This entry is indexed by nextLTMtransID for retrieval when a corresponding LTR is received.

The transmitting Bridge can maintain a separate sequence of LTM Transaction Identifiers per MEP if multiple MEPs in the same service instance and at the same MD Level have different MAC addresses, but uses a common sequence of LTM Transaction Identifiers for MEPs that share both of these characteristics.

In the case of a VID-based MA, the destination_address of an LTM is the group MAC address reserved for LTMs and appropriate to the MD Level of the originating MEP according to Table 8-19. In the case of a PBB-TE MEP, the destination_address of an LTM is the entry in the ESP-DA field of the 3-tuple of the MA's ESP that has the MEP's MAC address in its ESP-SA field. In the case of an SPBM VID MEP, the destination_address of an LTM is the individual B-MAC address of a remote system or the SPBM group MAC address (27.15) associated with an I-SID associated with the source MEP.

The Target MAC Address field [item c) in 12.14.7.4.2, 21.8.6] in the LTM can be any individual MAC address. However, since MEPs are required to periodically transmit CCMs, a MEP's MAC address is likely to be known to the MIPs along the path. Conversely, a MIP's MAC address, because the MIP does not initiate any CFM PDUs, can be unknown to intermediate Bridges unless it has recently replied to an LBM or LTM.

In the case of a PBB-TE MA, a PBB-TE MIP TLV is carried by the LTM, containing the Reverse VID [21.7.5.2, item e) in 12.14.7.4.2], to be used in the VID field by a MIP transmitted LTR, and, when the LTM is to be sent on a point-to-multipoint TESI, the Reverse MAC field (21.7.5.3) associated with MAC addresses to be used by the corresponding LTRs. The MIP MAC address field (21.7.5.1) in a PBB-TE MIP TLV associated with an LTM is null.

The MEP Linktrace Initiator in a Down MEP transmits the LTM through its Active SAP, toward the LAN attached to its Bridge Port. The MEP Linktrace Initiator in an Up MEP transmits the LTM through its MEP LTI SAP to its own Bridge's Linktrace Responder. That Linktrace Responder handles the LTM as described in 20.3.2. The Linktrace Responder can forward the LTM through the LOM Linktrace SAP and can respond through the MEP LTI SAP with an LTR. Thus, when an LTM is initiated in an Up MEP, the originating Bridge is the first hop.

[35] For this purpose, a pseudo-random value is sufficient, provided that the same value is not produced each time a system is reinitialized.

20.3.2 LTM reception, forwarding, and replying

An LTM at a particular MD Level is forwarded as an ordinary data frame until it encounters a MEP at an equal or higher MD Level, or an MHF at an equal MD Level. A MEP at a higher MD Level discards the LTM without further processing. An MP at an equal MD Level directs the LTM to its Bridge's Linktrace Responder. Since, for a given MD Level, different Bridge Ports on a given Bridge can be configured with MHFs, MEPs, both, or neither, an LTM can be both forwarded as ordinary data and processed by the Bridge's Linktrace Responder. An LTM that is originated by an Up MEP is forwarded directly to its Bridge's Linktrace Responder and not through the MEP's Active SAP toward the Frame filtering process.

The Linktrace Responder is responsible for processing and forwarding LTMs, and for replying to them with LTRs. All LTMs are subject to the validation criteria of 20.51.4; invalid or incorrectly addressed LTMs are discarded without further processing. After processing the LTM, the Linktrace Responder can return an LTR through the SAP on which the LTM was received and can forward at most one altered copy of the received LTM through an LOM on a different Bridge Port. It never forwards an LTM past a MEP at the LTM's own MD Level or higher, i.e., a MEP that bounds the LTM's MA. An LTM carries an LTM TTL field (21.8.4) that is decremented each time the LTM passes through a Linktrace Responder. The LTM is not forwarded if this field is 0 or 1 when the LTM is received.

The Linktrace Responder replies to the LTM if:

a) An ordinary data frame, with the same vlan_identifier as the LTM, a destination_address equal to the Target MAC Address field (21.8.6) of the LTM and received on the same Bridge Port as the LTM, would be forwarded through exactly one other Bridge Port (or to just the Management Port); or
b) The UseFDBonly bit of the Flags field of the LTM is 0, the Target MAC Address field (21.8.6) of the LTM is found in the Bridge's MIP CCM Database (19.3.10), and that entry in the MIP CCM Database identifies a Bridge Port (or the Management Port), other than the one on which the LTM was received; or
c) The MAC address of the MP that received the LTM equals the Target MAC Address field of the LTM;

and

d) LTM TTL field is nonzero when the LTM is received.

The single output Port identified in the preceding item a) or item b) is called the Egress Port. The Linktrace Responder forwards a copy of the LTM through the LOM on the Egress Port, with a new source_address parameter and the LTM TTL field decremented by 1, only if all of the following conditions are met:

e) An LTR was generated for the reasons specified in the preceding item a) or item b), but not item c);
f) The LTM was received via an MHF Linktrace SAP or a MEP LTI SAP, and not a MEP Linktrace SAP;
g) The Egress Port does not have a MEP at or above the LTM's MD Level; and
h) The received LTM TTL field was greater than 1.

The source_address parameter in the forwarded LTM does not change if the MA is associated to a TESI.

NOTE 1—When tracing the path to a known MAC address, all of the Bridges on a shared medium will receive the LTM. Making transmission of the LTR and forwarding of the LTM conditional on the FDB query ensures that at most one of those Bridges will reply. Similarly an LTM can be flooded, through a region of the network that has not yet learned the target MAC address, without provoking a storm of LTRs.

LTMs are forwarded immediately in order to minimize the time required to complete a Linktrace operation. LTRs are enqueued for delivery at a later time. If the LTM was received by a Down MEP or a Down MHF, the LTR includes a Reply Ingress TLV (21.9.8) describing that MP. If not received by a Down MEP, and if the Egress Port has an Up MEP or Up MHF configured for the LTM's MA, the LTR includes a Reply Egress

TLV (21.9.9). These TLVs report, to the originating MEP, the MIPs and/or the MEP along the path to the targeted MAC address.

If an LTM is forwarded to a shared medium LAN, and if one or more of the other Bridges attached to that LAN have only two Bridge Ports forwarding data for the LTM's vlan_identifier (including that shared medium), and if the MAC address in the LTM's Target MAC Address field (21.8.6) is not present in those Bridge's FDBs (or if the targeted MAC address is present in more than one Bridge's MIP CCM Database), then more than one of those receiving Bridges can respond to the LTM with an LTR. Also, an anomaly in the operation of Bridge or LAN, e.g., an FDB is recording its information incorrectly, can cause LTR responses along multiple paths.

The Reply TTL field in the LTR is sufficient for the originating MEP Linktrace Initiator to order the LTRs returned along a single path. The LTMs (21.8) also include the LTM Egress Identifier TLV (21.8.8). The LTRs (21.9) also include the LTR Egress Identifier TLV (21.9.7). The information in these TLVs allows the originating MEP to unambiguously construct the tree of paths taken by the LTM, if LTRs are returned along multiple paths.

NOTE 2—If an MA cannot be configured to transmit CCMs more quickly than Max Age causes MAC addresses to be removed from the Bridges' FDBs, then the best practice for the system administrator is to trigger an LTM transmission only after triggering a few LBMs to the target MAC address. This helps to ensure that the target MAC address is known to the intermediate Bridges, so that the LBM will return a result, and so that LTRs will be returned only along a single path.

NOTE 3—If unusual conditions prompt responses along multiple paths, the delay in transmitting the LTR reduces the chance that the originating MEP's receiving capabilities will be overwhelmed by the returned LTRs.

NOTE 4—The forwarded LTM uses, as its source address, the address of the MP through which the LTM is forwarded, not the source address of the original LTM. This means that a Bridge's Linktrace Responder need not be fully synchronized with its Relay Entity, as the latter can change the active topology rapidly without the risk of an adjacent Bridge learning the wrong direction for the source MAC address from an LTM. However, in the case of TESIs, the forwarded LTM simply uses the source address of the original LTM since the previous considerations do not apply in a PBB-TE Region. The LTM TTL field ensures that an LTM that is being processed while the active topology is changing will not be forwarded in a persistent loop.

The MEP Linktrace Initiator ignores any TLVs received in an LTR that do not violate the validation criteria of 20.51, but are not specified in this standard, and it ignores any valid Organization-Specific TLV not known to it. Except as otherwise specified in 20.47.3 and 20.47.4, all TLVs, whether known or ignored by the Linktrace Responder, are copied from the received LTM to the forwarded LTM, and from the received LTM to the LTR.

NOTE 5—Forwarding all unknown TLVs in both the LTM and the LTR enables future revisions of this standard, and designers of Organization-Specific TLVs, to add new capabilities.

20.3.3 LTR reception

LTRs are transmitted by a Linktrace Responder in response to a received LTM and returned in a unicast frame to the MEP Linktrace Initiator that originated the LTM. The MEP Linktrace Initiator validates the received LTR, discarding it if invalid, if the destination_address parameter does not match the MAC address of the Bridge Port on which the MEP resides, or if the LTR Transaction Identifier field does not match any of those stored in the MEP's Linktrace database (20.41.2), created when the LTM was originated.

Each validated LTR triggers the creation of a new entry in the Linktrace database, accessible as a managed object through the Read Linktrace Reply command (12.14.7.5). If no entry exists in the Linktrace database for this MEP, corresponding to the LTR Transaction Identifier field, the MEP Linktrace Initiator creates a new entry, with an index value [item c) in 12.14.7.5.2] of 1. If an entry does exist matching that field, it creates a new entry, with an index value one greater than the last matching LTR. In either case, the MEP Linktrace Initiator stores the contents of the LTR in this new entry.

See J.5 for a description of a method to reconstruct the path(s) taken by an LTM, based on the information in the Linktrace database.

20.4 CFM state machines

The relationships among a MEP's state machines are illustrated in Figure 20-1. That figure uses conventions similar to those of 13.24 and of Figure 13-13: open arrows denote variables that are set by one state machine and both read and set by another; closed arrows denote variables that are set by the owning state machine, and only read by other state machines. Not included in Figure 20-1 are the MEP Continuity Check Initiator state machine, the MP Loopback Responder state machine used in the MEP, and all of the MHF and Linktrace Responder state machines, because they operate independently.

20.5 CFM state machine timers

The timer variables declared in this subclause are part of the specification of the operation of CFM. The accompanying descriptions of their meaning and use are provided to aid in the comprehension of the protocol only and are not part of the specification.

One instance of the following shall be implemented:

a) LTFwhile (20.5.1)

One instance of the following shall be implemented per MEP:

b) CCIwhile (20.5.2)
c) errorCCMwhile (20.5.3)
d) xconCCMwhile (20.5.4)
e) LBIwhile (20.5.5)
f) FNGwhile (20.5.6)

One instance of the following shall be implemented per PBB-TE MEP implementing the Traffic field (21.6.1.4):

g) mmCCMwhile (20.5.7)
h) mmLocwhile (20.5.8)
i) mmFNGwhile (20.5.9)

One instance per MEP of the following shall be implemented for each remote MEP in the MEP's MA (those MEPs in the MA other than the MEP, itself):

j) rMEPwhile (20.5.10)

The "granularity" of a timer variable is the periodicity with which it is decremented.

20.5.1 LTFwhile

A timer variable used by the LTR Transmitter state machine to time out the expected transmission of LTRs.

20.5.2 CCIwhile

Timer counter for transmitting CCMs. CCIwhile has a granularity finer than or equal to 1/4 of the time represented by the CCMinterval variable.

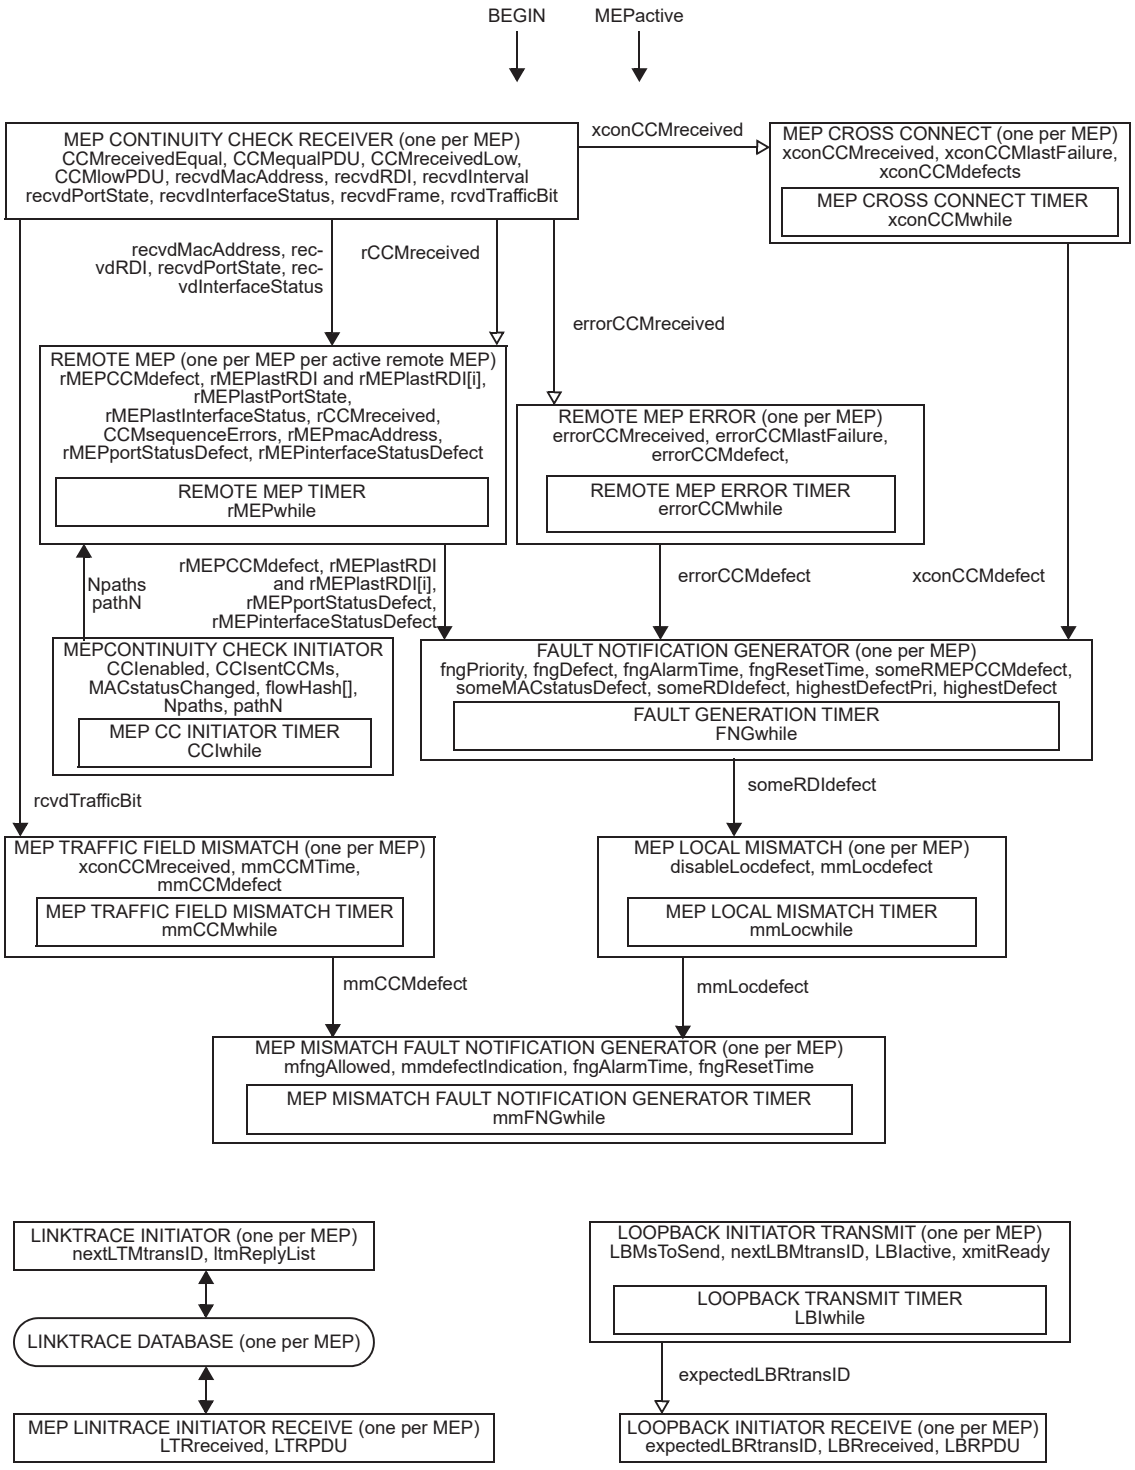

Figure 20-1—MEP state machines—overview and relationships

20.5.3 errorCCMwhile

Timer counter for timing out invalid CCMs. errorCCMwhile has a granularity finer than or equal to 1 ms.

20.5.4 xconCCMwhile

Timer counter for timing out cross connect CCMs. xconCCMwhile has a granularity finer than or equal to 1 ms.

20.5.5 LBIwhile

A timer variable used by the MEP Loopback Initiator transmit state machine to time out the expected reception of LBRs.

20.5.6 FNGwhile

A timer variable used by the MEP Fault Notification Generator state machine to wait for defects to stabilize and disappear.

20.5.7 mmCCMwhile

Timer counter for declaring mismatch defects based on the received Traffic field. mmCCMwhile has a granularity finer than or equal to 1 ms.

20.5.8 mmLocwhile

Timer counter for declaring mismatch defects based on inconsistencies in locally declared values (20.9.9). mmLocwhile has a granularity finer than or equal to 1 ms.

20.5.9 mmFNGwhile

A timer variable used by the MEP Mismatch Fault Notification Generator state machine (20.40) to wait for defects to stabilize and disappear.

20.5.10 rMEPwhile

Timer counter for timing out CCMs. rMEPwhile has a granularity finer than or equal to 1/4 of the time represented by the CCMinterval variable. A Bridge shall not set rMEPCCMdefect within (3.25 × CCMtime(CCMinterval)) seconds of the receipt of a CCM, and shall set rMEPCCMdefect within (3.5 × CCMtime(CCMinterval)) seconds after the receipt of the last CCM. This variable is readable as a managed object [item c) in 12.14.7.6.3].

NOTE—In order to generate a Defect upon the loss of three CCMs, but not generate a Defect when only two CCMs have been lost, a minimum resolution is required for rMEPwhile. The granularity specified for rMEPwhile, when used with the state machine in Figure 20-5, generates a Defect in a maximum of (3.5 × CCMtime(CCMinterval)) seconds, and a minimum of (3.25 × CCMtime(CCMinterval)) seconds.

20.6 CFM procedures

The following procedure is global to the system:

a) CCMtime() (20.6.1)

20.6.1 CCMtime()

CCMtime() takes, as a parameter, a value of the form used in the CCMinterval variable (20.8.1) and the CCM Interval field in a CCM PDU (21.6.1.3). It returns, as a value, the corresponding time interval, in the form used by the CCIwhile or rMEPwhile timer, as appropriate (20.5.2, 20.5.10).

20.7 Maintenance Domain variable

The following variable is local to a single Maintenance Domain and is accessible by more than one state machine:

a) mdLevel (20.7.1)

20.7.1 mdLevel

The integer MD Level of the Maintenance Domain. This variable is available as a managed object [item b) in 12.14.5.1.3].

20.8 MA variables

The following variable is local to a single MA and is accessible by more than one state machine:

a) CCMinterval (20.8.1)

20.8.1 CCMinterval

The configured time between CCM transmissions. The value configured for this variable shall be one of the nonzero values in Table 21-15. This variable is available as a managed object [item e) in 12.14.6.1.3].

20.9 MEP variables

The following variables are local to a single MEP and are accessible by more than one state machine:

a) MEPactive (20.9.1)
b) enableRmepDefect (20.9.2)
c) MAdefectIndication (20.9.3)
d) allRMEPsDead (20.9.4)
e) lowestAlarmPri (20.9.5)
f) presentRDI (20.9.6)
g) MEPprimaryVID (20.9.7)

The following variables may be present only in PBB-TE MAs, are local to a single PBB-TE MEP and are accessible by more than one state machine:

h) presentTraffic (20.9.8)
i) presentmmLoc (20.9.9)

The following variables are present only in Infrastructure Segment MAs, are local to a single Infrastructure Segment MEP, and are accessible by more than one state machine:

j) ISpresentTraffic (20.9.10)
k) ISpresentmmLoc (20.9.11)

The following variable is present only in ECMP path MAs, is local to a single ECMP path MEP, and is accessible by more than one state machine:

l) EpMEP (20.9.12)

20.9.1 MEPactive

A Boolean indicating the administrative state of the MEP. True indicates that the MEP is to function normally, and false that it is to cease functioning. This variable is available as a managed object [item e) in 12.14.7.1.3].

NOTE—MEPactive controls the BEGIN input to the MEP state machines. Therefore, for any MEP that has been completely configured, it is as much an indication of the operative state of the MEP as a control over that state.

20.9.2 enableRmepDefect

A Boolean indicating whether frames on the service instance monitored by this MEP's MA are enabled to pass through this Bridge Port by the spanning tree protocol (Clause 13) and VLAN topology management (Clause 11). Set true either if they are enabled, or if the MEP is not associated with a single value of the Port State and VID member set, else false. In a Bridge, the value of enableRmepDefect is determined from the Port State (8.4) of the spanning tree instance that controls the MEP's Primary VID, and that VID's member set (8.8.10), as shown in Table 20-2. This variable also controls the value output in the Port Status TLV (21.5.4).

Table 20-2—Deriving enableRmepDefect and Port Status TLV in a Bridge

Port State (8.4)	Bridge Port in Primary VID's member set	Port Status TLV (21.5.4)	enableRmepDefect
Disabled, blocked, listening, broken, discarding [a] or learning		psBlocked	False
Forwarding	No	psBlocked	False
	Yes	psUp	True

[a] "Discarding" is used in place of the values disabled, blocked, listening, or broken defined in IETF RFC 4318.

A MEP that is:

a) Configured in an MA that is not associated with a VID
b) On a Bridge that is running multiple instances of the spanning tree
c) On a Bridge Port that is not excluded by Static VLAN Registration Entries from membership in VIDs belonging to more than one spanning tree instance

can be unable to generate an unambiguous value for the Port Status TLV, because different MSTIs can be in different Port States. For a MEP in that position, enableRmepDefect is always true.

20.9.3 MAdefectIndication

A Boolean indicating the operational state of the MEP's MA. True indicates that at least one of the remote MEPs configured on this MEP's MA has failed, and false indicates either that all are functioning, or that the MEP has been active for less than the time-out period. MAdefectIndication is true whenever an enabled defect is indicated. That is, MAdefectIndication is true if and only if, for one or more of the variables someRDIdefect, someRMEPCCMdefect, someMACstatusDefect, errorCCMdefect, or xconCCMdefect, that variable is true and the corresponding priority of that variable from Table 20-1 is greater than or equal to the value of the variable lowestAlarmPri.

20.9.4 allRMEPsDead

A Boolean indicating that this MEP is receiving none of the remote MEPs' CCMs. allRMEPsDead is the logical AND of all of the rMEPCCMdefect variables.

20.9.5 lowestAlarmPri

An integer value indicating the lowest defect priority (see Table 20-1) that can trigger the generation of a Fault Alarm. This variable is a managed object [item k) in 12.14.7.1.3].

20.9.6 presentRDI

A Boolean value indicating the state of the RDI bit in CCMs transmitted by this MEP. presentRDI is true if and only if one or more of the variables someRMEPCCMdefect, someMACstatusDefect, errorCCMdefect, or xconCCMdefect is true, and if the corresponding priority of that variable, from Table 20-1, is greater than or equal to the value of the variable lowestAlarmPri.

20.9.7 MEPprimaryVID

An integer specifying a VID, one of the VIDs assigned to the MEP's MA, which is to be used as the Primary VID for this MEP. This variable is related to the managed object item d) in 12.14.7.1.3. It is not necessarily numerically equal to that object, however. MEPprimaryVID always contains the numerical value of the Primary VID. The managed object may contain 0, to indicate that the Primary VID is that of the MEP's MA, or contain the Primary VID itself, if the MA's VID is overridden for this particular MEP. In the case of a MEP associated with a PBB-TE MA, this value is not directly configurable but it takes the value of the ESP-VID field in the 3-tuple of the PBB-TE MA's ESP that has the MEP's MAC address in its ESP-SA field.

20.9.8 presentTraffic

A Boolean value indicating if at least one backbone service instance is configured to use the TESI's ESP upon which this PBB-TE MEP is transmitting CCMs. presentTraffic is TRUE if and only if the Backbone Service Instance table, of the CBP associated with this MEP, contains an entry that has in its B-VID and Default Backbone Destination fields the values of ESP-VID and ESP-DA of the monitored TESI's ESP that originates at the MEP.

20.9.9 presentmmLoc

presentmmLoc is the logical AND of presentRDI (20.9.6) and presentTraffic (20.9.8).

20.9.10 ISpresentTraffic

A Boolean value indicating if at least one TESI protected by the IPG is configured to use the segment monitored by the Infrastructure Segment MEP. ISpresentTraffic is TRUE if and only if the port upon which this MEP is configured is the outbound port of the entry in the FDB corresponding to the TESI protected by the IPG.

20.9.11 ISpresentmmLoc

ISpresentmmLoc is the logical AND of presentRDI (20.9.6) and ISpresentTraffic (20.9.10).

20.9.12 EpMEP

Boolean. This variable is used to condition actions related to ECMP path MEPs. It is true for ECMP path MEPs and false otherwise.

20.10 MEP Continuity Check Initiator variables

The following variables are local to the MEP Continuity Check Initiator state machine:

a) CCIenabled (20.10.1)
b) CCIsentCCMs (20.10.2)
c) MACstatusChanged (20.10.3)
d) Npaths (20.10.4)
e) flowHash[] (20.10.5)
f) pathN (20.10.6)
g) CCMcnt (20.10.7)

20.10.1 CCIenabled

Controls the transmission of CCMs. When set to true, CCMs are transmitted. When set to false, CCM transmission ceases. This variable is available as a managed object [item g) in 12.14.7.1.3].

20.10.2 CCIsentCCMs

Integer value. CCIsentCCMs is initialized to 1 when the MEP is created and may be used thereafter by xmitCCM() to fill the Sequence Number field of a transmitted CCM. This variable is available as a managed object [item w) in 12.14.7.1.3].

20.10.3 MACstatusChanged

Boolean. MACstatusChanged triggers the transmission of one extra CCM. If the Port Status TLV (21.5.4) or Interface Status TLV (21.5.5) is being transmitted by the MEP, and if CCMinterval indicates a transmission interval of 10 s or slower, MACstatusChanged is set to true whenever the value reported in either of those two TLVs changes. MACstatusChanged is reset to false by the MEP Continuity Check Initiator state machine.

20.10.4 Npaths

Integer value. The number of paths being tested by this MEP. The value is 1 (default) except in the case of ECMP path MEPs that may test a set of paths by using one destination address and different flow hash values.

20.10.5 flowHash[ ]

This variable is applicable only for ECMP path MEPs.

Array of 16-bit values. A set of flow hash values used to test a set of paths to a given destination address. The default is a single NULL value.

20.10.6 pathN

This variable is applicable only for ECMP path MEPs.

Integer value in the range 0..(Npaths – 1) and all arithmetic using this variable is modulo Npaths. The index of the current path (flow hash) being used in CCMs sent from the MEP. This value is shared with the Remote MEP state machine to enable correlation of received RDIs with the cycle of paths being tested.

20.10.7 CCMcnt

This variable is applicable only for ECMP path MEPs.

Integer value in the range 0..3 and all arithmetic using this variable is modulo 4. This variable is a counter used to send each flowHash[] value in four successive CCMs.

20.11 MEP Continuity Check Initiator procedures

The following procedure is local to the MEP Continuity Check Initiator state machine:

a) xmitCCM() (20.11.1)

20.11.1 xmitCCM()

xmitCCM() constructs and transmits a CCM on the Active SAP using an M_UNITDATA.request as follows:

a) Sets the destination_address parameter to the value from Table 8-18 corresponding to the MEP's MD Level. In the case of a PBB-TE associated MEP, SPBM path MEP, or ECMP path MEP, the destination_address parameter is set to the MAC address indicated by the ESP-DA field of the ESP having in its ESP-SA field the MAC address of the MEP. In the case of an SPBM VID MEP (27.18.1), the destination_address parameter is set to the SPBM group MAC address (27.15) associated with the source MEP and the SPBM default I-SID. In the case of an SPBM group MEP, the destination_address parameter is set to the SPBM group MAC address (27.15) assigned to the source MEP's CBP for the SPBM group MA's I-SID.
b) Sets the source_address parameter to the MAC address of the MEP [item i) in 12.14.7.1.3].
c) Sets the priority parameter according to the MEP's managed objects [item h) in 12.14.7.1.3].
d) Sets the drop_eligible parameter to false.
e) In the case of ECMP with flow filtering, the time_to_live and flow_hash parameters must be set. The time_to_live parameter is set to the TTL Value in the Flow Filtering Control Table entry on the CBP for the source MEP's VID [item d) in 12.16.5.5.2]. In the case of an SPBM VID MEP or SPBM group MEP, the flow_hash parameter is set to zero. In the case of an ECMP path MEP, the flow_hash parameter is set to the value of flowHash[pathN].
f) Places the MEP's MD Level (20.7.1) in the MD Level field (21.4.1).
g) Fills the CCM Interval field (21.6.1.3) with the CCM transmission interval [20.8.1, item e) in 12.14.6.1.3].
h) Fills the RDI field (21.6.1.1) with the presentRDI variable (20.9.6).
i) Should copy CCIsentCCMs (20.10.2) to the Sequence Number field of the CCM (21.6.3), else copies 0 into that field.
j) Places the MEP's MAID into the appropriate fields of the CCM [item a) in 12.14.1.2.2, item b) in 12.14.5.3.2, and 21.6.5.1 through 21.6.5.6].
k) Places the MEP's MEPID [item g) in 12.14.6.1.3] into the Maintenance association Endpoint Identifier field (21.6.4).
l) As controlled by the managed objects item e) in 12.14.3.1.3, item d) in 12.14.5.1.3, and item d) in 12.14.6.1.3, places a Sender ID TLV (21.5.3) in the CCM, identifying the transmitting system.
m) Optionally, places a Port Status TLV (21.5.4) in the CCM, reporting the status of the Bridge Port.
n) Optionally, places an Interface Status TLV (21.5.5) in the CCM, reporting the status of the Bridge Port.

o) Increments CCIsentCCMs by 1, wrapping around from 232 – 1 to 0.
p) Only in the case of a PBB-TE MEP, optionally fills the Traffic field (21.6.1.4) with the presentTraffic variable (20.9.8).
q) Only in the case of an Infrastructure Segment MEP, optionally fills the Traffic field (21.6.1.4) with the value ISpresentTraffic (20.9.10).

20.12 MEP Continuity Check Initiator state machine

Each MEP Continuity Check Initiator (19.2.9) instantiates one MEP Continuity Check Initiator state machine. The MEP Continuity Check Initiator state machine implements the function specified by the state diagram in Figure 20-2, the variable declarations in 20.10 and the procedures in 20.11.

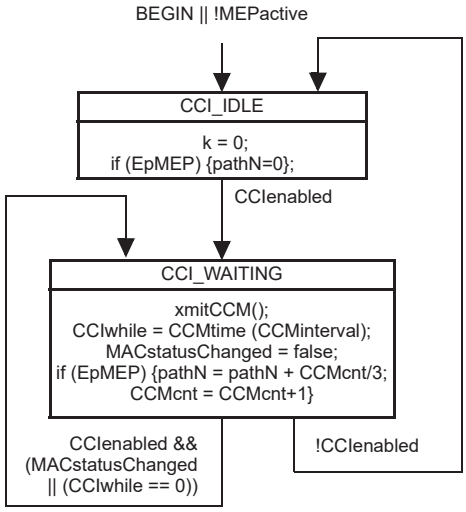

Figure 20-2—MEP Continuity Check Initiator state machine

NOTE—Figure 20-2 indicates that the setting of MACstatusChanged causes CCIwhile to be reset and thus changes the phase of the CCM transmission cycle. An alternative formulation of state machine could transmit an extra CCM, but not reset CCIwhile. Whether setting MACstatusChanged in a MEP causes CCIwhile to be reset is not specified by this standard.

20.13 MHF Continuity Check Receiver variables

The following variables are defined for the MHF Continuity Check Receiver:

a) MHFrecvdCCM (20.13.1)
b) MHFCCMPDU (20.13.2)

20.13.1 MHFrecvdCCM

A Boolean value set to true by the MHF OpCode Demultiplexer (19.3.6) when a CCM at the MHF's MD Level is received. Cleared by the MHF Continuity Check Receiver state machine.

20.13.2 MHFCCMPDU

Structure. Loaded with the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the CCM PDU received by the MHF OpCode Demultiplexer (19.3.6) when a CCM at the MHF's MD Level is received.

20.14 MHF Continuity Check Receiver procedures

The following procedure is defined for the MHF Continuity Check Receiver:

a) MHFprocessCCM() (20.14.1)

20.14.1 MHFprocessCCM()

MHFprocessCCM() shall validate the received CCM according to 20.51.4 and discard the received CCM if invalid. Otherwise, MHFprocessCCM() records the FID, source_address, and Port number of the received CCM in the MHF's MIP CCM Database.

20.15 MHF Continuity Check Receiver state machine

The MHF Continuity Check Receiver state machine implements the functions specified by the state diagram in Figure 20-3, using the variables in 20.13 and procedures in 20.14.

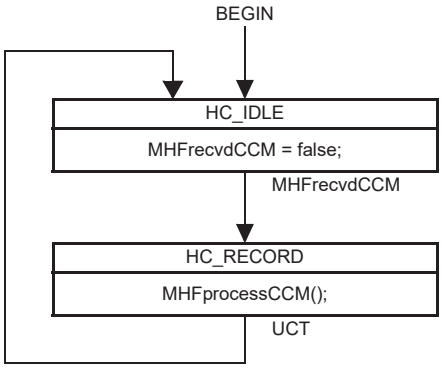

Figure 20-3—MHF Continuity Check Receiver state machine

20.16 MEP Continuity Check Receiver variables

The following variables are defined for the MEP Continuity Check Receiver:

a) CCMreceivedEqual (20.16.1)
b) CCMequalPDU (20.16.2)
c) CCMreceivedLow (20.16.3)
d) CCMlowPDU (20.16.4)
e) recvdMacAddress (20.16.5)
f) recvdRDI (20.16.6)
g) recvdInterval (20.16.7)
h) recvdPortState (20.16.8)
i) recvdInterfaceStatus (20.16.9)
j) recvdSenderId (20.16.10)
k) recvdFrame (20.16.11)
l) CCMsequenceErrors (20.16.12)

The following variable is present only in PBB-TE MEP or Infrastructure Segment MEP that supports the Traffic field (21.6.1.4), is local to a single PBB-TE MEP or Infrastructure Segment MEP, and is accessible by the MEP Mismatch state machines (20.26):

m) rcvdTrafficBit (20.16.13)

20.16.1 CCMreceivedEqual

Boolean flag. Set by the MEP Equal OpCode Demultiplexer (19.2.7) when a CCM at the MEP's MD Level is received. Cleared by the MEP Continuity Check Receiver state machine.

20.16.2 CCMequalPDU

Structure. Loaded with the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the CCM PDU received by the MEP Equal OpCode Demultiplexer (19.2.7) when a CCM at the MEP's MD Level is received.

20.16.3 CCMreceivedLow

Boolean flag. Set by the MEP Low OpCode Demultiplexer (19.2.7) when a CCM below the MEP's MD Level is received. Cleared by the MEP Continuity Check Receiver state machine.

20.16.4 CCMlowPDU

Structure. Loaded with the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the CCM PDU received by the MEP Low OpCode Demultiplexer (19.2.7) when a CCM below the MEP's MD Level is received.

20.16.5 recvdMacAddress

Set by the MEPprocessEqualCCM() procedure with the source_address from the last-received CCM from the remote MEP served by this copy of the Remote MEP state machine.

20.16.6 recvdRDI

Boolean flag. Set by MEPprocessEqualCCM() according to the RDI field of the last-received valid CCM.

20.16.7 recvdInterval

Timer counter indicating timer counter equivalent of the value encoded in the CCM Interval field of a received CCM. Set by MEPprocessEqualCCM().

20.16.8 recvdPortState

(optional) Enumerated variable indicating the contents of the Port Status TLV (21.5.4) of the last-received valid CCM or psNoPortStateTLV: Indicates either that no CCM has been received or that no Port Status TLV was present in the last CCM received. Set by MEPprocessEqualCCM().

20.16.9 recvdInterfaceStatus

(optional) Enumerated variable indicating the contents of the Interface Status TLV (21.5.5) of the last-received valid CCM or isNoInterfaceStatusTLV: Indicates either that no CCM has been received or that no Interface Status TLV was present in the last CCM received. Set by MEPprocessEqualCCM().

20.16.10 recvdSenderId

(optional) Enumerated variable indicating the contents of the Sender ID TLV (21.5.3) of the last-received valid CCM or isNoSenderIdTLV: Indicates either that no CCM has been received or that no Sender ID TLV was present in the last CCM received. Set by MEPprocessEqualCCM().

20.16.11 recvdFrame

Octet string holding a frame received by MEPprocessEqualCCM(). recvdFrame can be reconstructed either from the M_UNITDATA.indication information presented to the MEP through the Active SAP, or from the EM_UNITDATA.indication presented to the EISS Multiplex Entity. The size of recvdFrame indicates the size of the reconstructed frame. When set to the value NULL, the size of recvdFrame is 0.

20.16.12 CCMsequenceErrors

The total number of out-of-sequence CCMs received from all remote MEPs. This variable is readable as a managed object [item v) in 12.14.7.1.3].

20.16.13 rcvdTrafficBit

Boolean flag that is applicable only for PBB-TE MEPs and Infrastructure Segment MEPs supporting the Traffic field (21.6.1.4). Set by MEPprocessEqualCCM() according to the Traffic field of the last-received valid CCM.

20.17 MEP Continuity Check Receiver procedures

The following procedures are defined for the Continuity Check Receiver:

a) MEPprocessEqualCCM() (20.17.1)
b) MEPprocessLowCCM() (20.17.2)

20.17.1 MEPprocessEqualCCM()

Called by the MEP Continuity Check Receiver state machine whenever a CCM is received at the MD Level of the MEP. MEPprocessEqualCCM() processes the CCM contained in CCMequalPDU as follows:

a) MEPprocessEqualCCM() shall process the CCM according to 20.51.4.2, and may validate the CCM according to 20.51.4.3, and discard any frames that fail the validation.
b) Otherwise, if the MAID of the received CCM does not exactly match the MAID configured in the receiving MEP [item a) in 12.14.1.2.2, item b) in 12.14.5.3.2], then MEPprocessEqualCCM() sets xconCCMreceived (20.23.1) true (this procedural step being optional in the case of a PBB-TE MEP or Infrastructure Segment MEP, SPBM path MEP, or ECMP path MEP), reconstructs the frame containing the CCM into recvdFrame, and places a timer counter value into recvdInterval corresponding to the value of the CCM Interval field in the received CCM.
c) Otherwise, if:
    1) MEPID in the received CCM is not configured in the receiving MEP [item g) in 12.14.6.1.3], or
    2) MEPID in the received CCM matches the MEPID of the receiving MEP [item b) in 12.14.6.3.2], or
    3) CCM Interval field in the received CCM does not match that configured for the receiving MEP [item e) in 12.14.6.1.3],

then MEPprocessEqualCCM() sets errorCCMreceived (20.21.1) true, reconstructs the frame containing the CCM into recvdFrame, and places a timer counter value into recvdInterval corresponding to the value of the CCM Interval field in the received CCM.

d) Otherwise, MEPprocessEqualCCM()
   1) Copies the source_address parameter into recvdMacAddress.
   2) Copies the RDI field to recvdRDI.
   3) Optionally copies the Port Status TLV to recvdPortState.
   4) Optionally copies the Interface Status TLV to recvdInterfaceStatus.
   5) Optionally copies the Sender ID TLV to recvdSenderId.
   6) Optionally updates the Bridge's MIP CCM Database.
   7) Sets the rCCMreceived variable (20.19.6) for the particular instance of the Remote MEP state machine corresponding to the Maintenance association Endpoint Identifier field in the CCM.
   8) Only in the case of a PBB-TE MEP or Infrastructure Segment MEP, optionally copies the Traffic field (21.6.1.4) to rcvdTrafficBit (20.16.13).

MEPprocessEqualCCM() should also:

e) Compare the Sequence Number field in the received CCM to the value saved in the MEP CCM Database.
f) If both values are not 0, and if the new value is not 1 greater than the last, increment CCMsequenceErrors (20.16.12).
g) Store the received Sequence Number in the MEP CCM Database.

20.17.2 MEPprocessLowCCM()

Called by the MEP Continuity Check Receiver state machine whenever a CCM is received with an MD Level that is less than the MEP's MD Level (mdLevel, 20.7.1). MEPprocessLowCCM() processes the CCM contained in CCMlowPDU as follows:

a) MEPprocessLowCCM() shall process the CCM according to 20.51.4.2, and may validate the CCM according to 20.51.4.3, and discard any frames that fail the validation.
b) Otherwise, MEPprocessLowCCM() sets xconCCMreceived (20.23.1) true, reconstructs the frame containing the CCM into recvdFrame, and places a timer counter value into recvdInterval corresponding to the value of the CCM Interval field in the received CCM.

20.18 MEP Continuity Check Receiver state machine

The MEP Continuity Check Receiver state machine implements the functions specified by the state diagram in Figure 20-4, using the variables in 20.16 and procedures in 20.17.

20.19 Remote MEP variables

The following variables are local to the Remote MEP state machine:

a) rMEPCCMdefect (20.19.1)
b) rMEPlastRDI and rMEPlastRDI[i] (20.19.2)
c) rMEPlastPortState (20.19.3)
d) rMEPlastInterfaceStatus (20.19.4)
e) rMEPlastSenderId (20.19.5)
f) rCCMreceived (20.19.6)
g) rMEPmacAddress (20.19.7)

h) rMEPportStatusDefect (20.19.8)
i) rMEPinterfaceStatusDefect (20.19.9)
j) lastPathN (20.19.10)

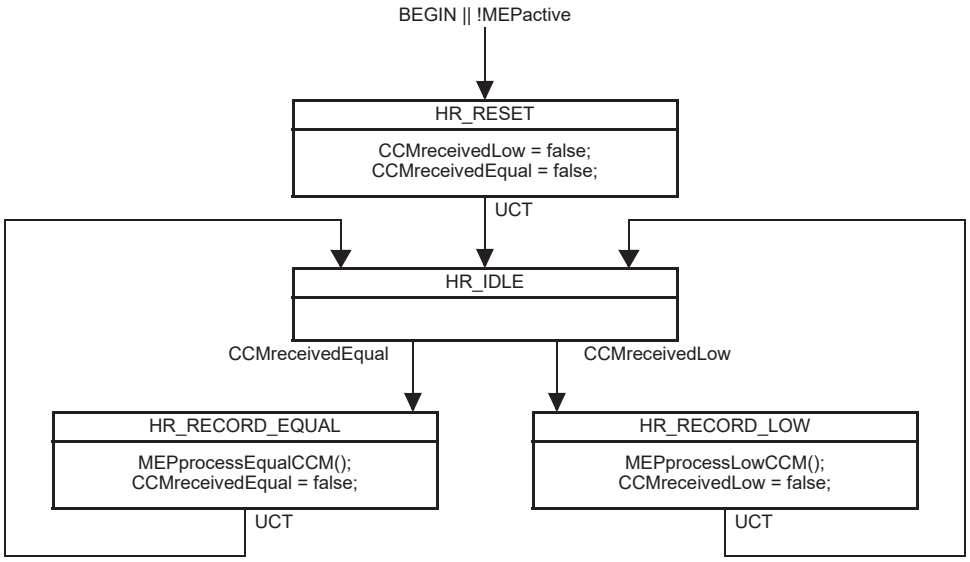

Figure 20-4—MEP Continuity Check Receiver state machine

20.19.1 rMEPCCMdefect

Reports the state of the remote MEP. When true, no CCM has been received from the remote MEP for at least (3.25 × CCMtime(CCMinterval)) seconds.

20.19.2 rMEPlastRDI and rMEPlastRDI[i]

Boolean flag. Contains the RDI flag from the last-received CCM. This variable is readable as a managed object [item e) in 12.14.7.6.3]. In the case of an ECMP path MEP, if Npaths > 1, there is a set of variables rMEPlastRDI[i] of size Npaths (20.10.4). In this case the variable rMEPlastRDI is the logical OR of the members of the set rMEPlastRDI[i]. Each member of the set rMEPlastRDI[i] is set if an RDI is received while pathN == i and is reset if no RDI is received while pathN == i in the last CCM cycle of the MEP Continuity Check Initiator state machine.

20.19.3 rMEPlastPortState

Enumerated value. Contains the value obtained from the Port Status TLV (21.5.4) of the last-received CCM or a value indicating that the last-received CCM contained no Port Status TLV. This variable is readable as a managed object [item f) in 12.14.7.6.3].

20.19.4 rMEPlastInterfaceStatus

Enumerated value. Contains the value obtained from the Interface Status TLV (21.5.5) of the last-received CCM or a value indicating that the last-received CCM contained no Interface Status TLV. This variable is readable as a managed object [item g) in 12.14.7.6.3].

20.19.5 rMEPlastSenderId

Enumerated value. Contains the value obtained from the Sender ID TLV (21.5.3) of the last-received CCM or a value indicating that the last-received CCM contained no Sender ID TLV. This variable is readable as a managed object [item h) in 12.14.7.6.3].

20.19.6 rCCMreceived

Boolean flag set true by MEPprocessEqualCCM() to indicate that a CCM has been received that matches the configured expectations of a particular Remote MEP state machine. Cleared to false by the Remote MEP state machine.

20.19.7 rMEPmacAddress

One field in each entry in the MEP CCM Database for a remote MEP, containing source_address of the last-received CCM from that remote MEP. This variable is readable as a managed object [item d) in 12.14.7.6.3].

20.19.8 rMEPportStatusDefect

A Boolean indicating that the remote MEP is reporting a failure in its Port Status TLV (21.5.4). It is true only if the last received CCM contained a Port Status TLV that contained some value other than psUp, i.e., the remote MEP's Bridge Port is not forwarding data. It is equal to (rMEPlastPortState!= psUp && rMEPlastPortState!= psNoPortStateTLV: Indicates either that no CCM has been received or that no Port Status TLV was present in the last CCM received).

20.19.9 rMEPinterfaceStatusDefect

A Boolean indicating that the remote MEP is reporting a failure in its Interface Status TLV (21.5.5). It is true only if the last received CCM contained an Interface Status TLV that contained some value other than isUp, i.e., the remote MEP's Bridge Port is not available for forwarding data. It is equal to (rMEPlastInterfaceStatus!= isUp && rMEPlastInterfaceStatus!= isNoInterfaceStatusTLV: Indicates either that no CCM has been received or that no Interface Status TLV was present in the last CCM received).

20.19.10 lastPathN

This variable is applicable only for ECMP path MEPs.

Integer value. The variable lastPathN holds the previous value of the pathN variable.

20.20 Remote MEP state machine

The Remote MEP state machine implements the function specified by the state diagram in Figure 20-5 and the variable declarations in 20.19, and utilizes the procedures in 20.17.

20.21 Remote MEP Error variables

The following variables are local to the Remote MEP Error state machine:

a) errorCCMreceived (20.21.1)
b) errorCCMlastFailure (20.21.2)
c) errorCCMdefect (20.21.3)

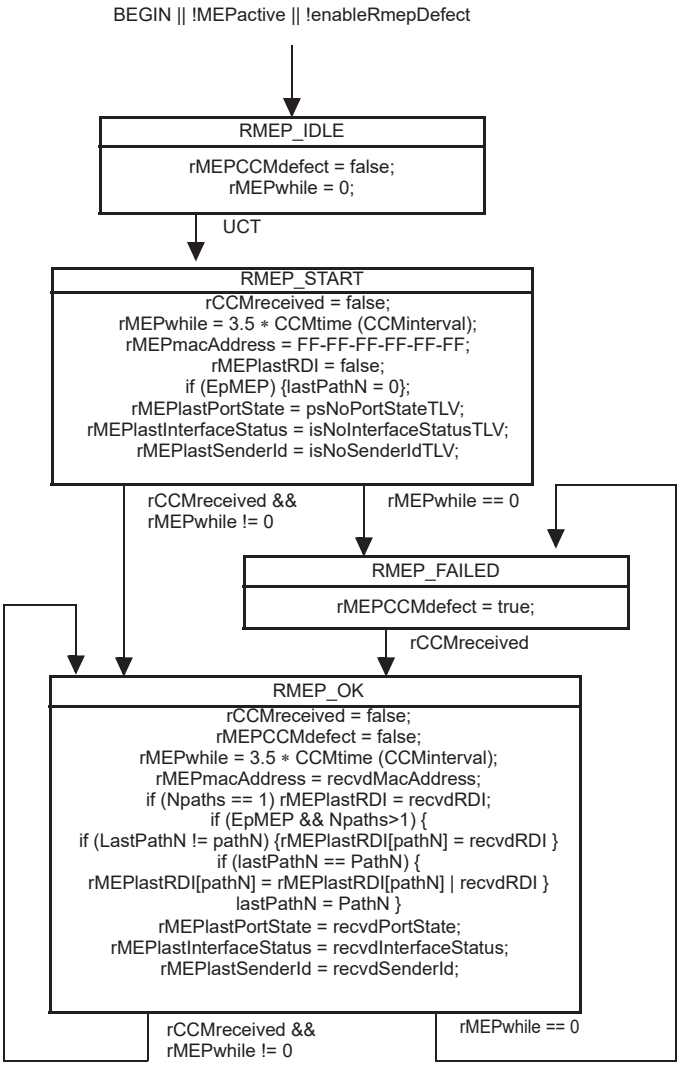

Figure 20-5—Remote MEP state machine

20.21.1 errorCCMreceived

Boolean flag set true by MEPprocessEqualCCM() if an invalid CCM is received. Cleared to false by the Remote MEP Error state machine.

20.21.2 errorCCMlastFailure

Octet string with the same characteristics as recvdFrame. Value controlled by the Remote MEP Error state machine. Readable as a managed object [item t) in 12.14.7.1.3]. Size is sufficient to retain a frame containing a maximum-length CCM in errorCCMlastFailure.

20.21.3 errorCCMdefect

A Boolean flag set and cleared by the Remote MEP Error state machine to indicate that one or more invalid CCMs has been received, and that 3.5 times that CCM's transmission interval has not yet expired. This variable is readable as a managed object [item r) in 12.14.7.1.3].

20.22 Remote MEP Error state machine

The Remote MEP Error state machine implements the function specified by the state diagram in Figure 20-6 and the variable declarations in 20.21.

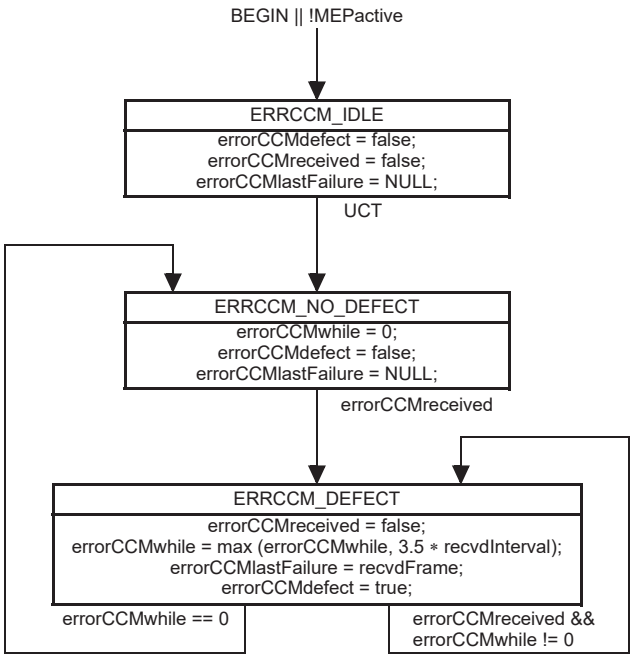

Figure 20-6—Remote MEP Error state machine

20.23 MEP Cross Connect variables

The following variables are local to the MEP Cross Connect state machine:

a) xconCCMreceived (20.23.1)
b) xconCCMlastFailure (20.23.2)
c) xconCCMdefect (20.23.3)

20.23.1 xconCCMreceived

Boolean flag set true by MEPprocessEqualCCM() when a cross connect CCM is received. Cleared to false by the MEP Cross Connect state machine.

20.23.2 xconCCMlastFailure

Octet string with the same characteristics as recvdFrame. Value controlled by the MEP Cross Connect state machine. Readable as a managed object [item u) in 12.14.7.1.3]. Size is sufficient to retain a frame containing a maximum-length CCM.

20.23.3 xconCCMdefect

A Boolean flag set and cleared by the MEP Cross Connect state machine to indicate that one or more cross connect CCMs has been received, and that 3.5 times of at least one of those CCMs' transmission interval has not yet expired. This variable is readable as a managed object [item s) in 12.14.7.1.3].

20.24 MEP Cross Connect state machine

The MEP Cross Connect state machine implements the function specified by the state diagram in Figure 20-7 and the variable declarations in 20.23.

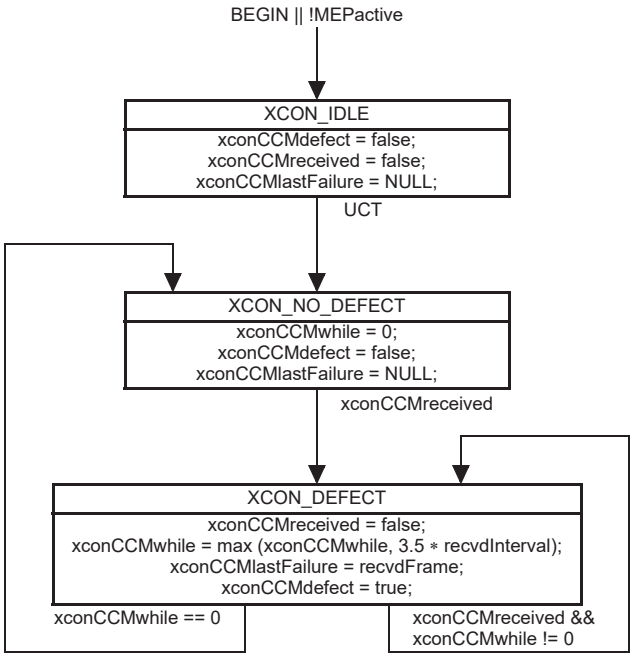

Figure 20-7—MEP Cross Connect state machine

20.25 MEP Mismatch variables

The following variables are local to the MEP Mismatch state machines for a PBB-TE MEP or Infrastructure Segment MEP implementing the Traffic field (21.6.1.4):

a) mmCCMreceived (20.25.1)
b) mmCCMdefect (20.25.2)
c) mmCCMTime (20.25.3)
d) disableLocdefect (20.25.4)
e) mmLocdefect (20.25.5)

20.25.1 mmCCMreceived

Boolean flag set to TRUE when rcvdTrafficBit (20.16.13) does not match the presentTraffic (20.9.8) in the case of a PBB-TE MEP or rcvdTrafficBit (20.16.13) does not match the ISpresentTraffic (20.9.10) in the case of an Infrastructure segment MEP.

20.25.2 mmCCMdefect

A Boolean flag set and cleared by the MEP Mismatch state machines to indicate that one or more CCMs with Traffic fields not matching the presentTraffic (20.9.8) have been received in the case of a state machine associated with a PBB-TE MEP or that one or more CCMs with ISpresentTraffic (20.9.10) has been received in the case of a state machine associated with an Infrastructure Segment MEP, over a period that is greater than 3.5 times the configured CCM transmission rate and given by the mmCCMTime (20.25.3). This variable is readable as a managed object [item ah) in 12.14.7.1.3].

20.25.3 mmCCMTime

The time used to initiate the mmCCMwhile timer. This is the time taken for a remote IB-BEB to send a CCM with the correct information in the Traffic field and is tied to the target protection switching time, i.e., 50 ms, as a mismatch would be normal prior to the completion of a protection switch. In the most generic case it is equal to the Detection Time + Restoration Procedure Time + Restoration Transfer time. This gives a time of 3.5 × CCM interval + Restoration Procedure Time + 1.25 × CCM interval. As a result its value is set to max (50 ms, 4.75 × CCMtime (CCMinterval) + 10 ms).

20.25.4 disableLocdefect

A Boolean that disables the indication of the mmLocdefect. The variable is always set to TRUE for PBB-TE MAs that are not part of a TE protection group. On a PBB-TE MEP associated with the working entity in one or more TE protection groups to which its monitoring TESI MA is assigned, disableLocdefect is TRUE if and only if either p.SF (26.10.3.3.2) or LoP (26.10.3.3.4) is TRUE on any of these TE protection groups. On a PBB-TE MEP associated with only one protection entity in all the TE protection groups to which it is assigned, disableLocdefect is TRUE if and only if FS (26.10.3.3.5) is TRUE on this TE protection group.

20.25.5 mmLocdefect

A Boolean flag set and cleared by the MEP Local Mismatch state machine to indicate that presentmmLoc (20.9.9) or ISpresentmmLoc (20.9.11) is set to TRUE, over a period of 50 ms [item ai) in 12.14.7.1.3].

20.26 MEP Mismatch state machines

The MEP Mismatch state machines implement the functions specified by the state diagrams in Figure 20-8, Figure 20-9, and the variable declarations in 20.25. There is one MEP Traffic Field Mismatch state machine and one MEP Local Mismatch state machine per PBB-TE MEP or Infrastructure Segment MEP implementing the Traffic field (21.6.1.4).

20.27 MP Loopback Responder variables

The following variables are local to the MP Loopback Responder state machine:

a) LBMreceived (20.27.1)
b) LBMPDU (20.27.2)

20.27.1 LBMreceived

Boolean variable, set to true by an MP OpCode Demultiplexer when an LBM is received, and cleared by an MP Loopback Responder state machine.

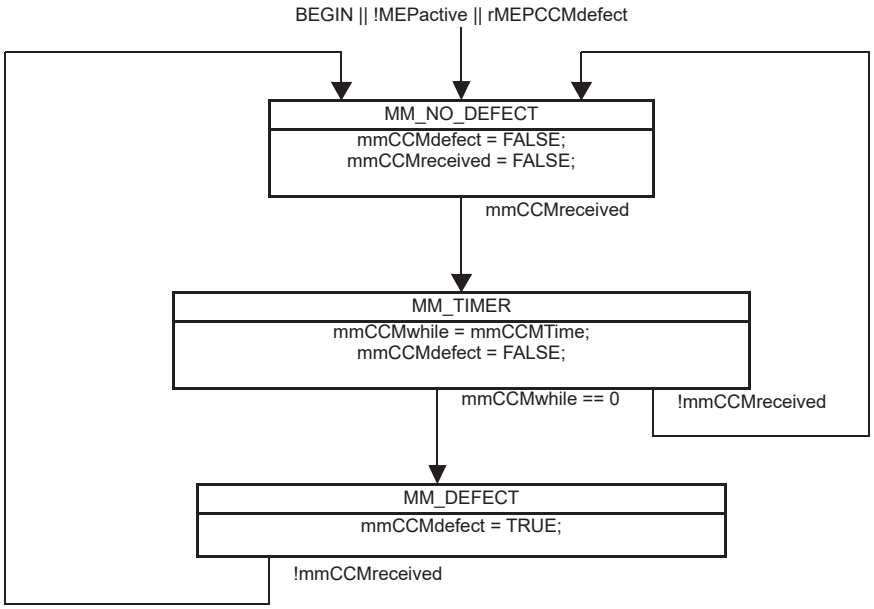

Figure 20-8—MEP Traffic Field Mismatch state machine

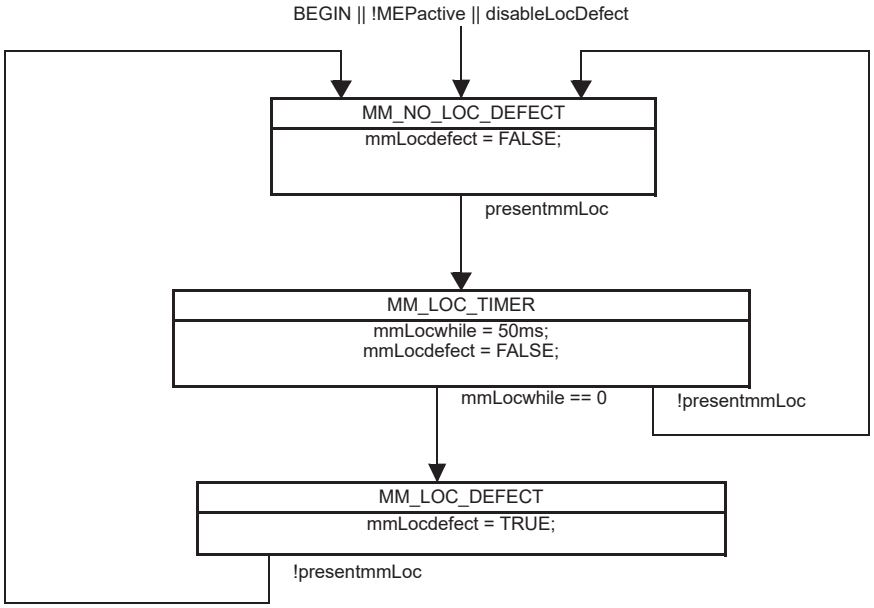

Figure 20-9—MEP Local Mismatch state machine

20.27.2 LBMPDU

Structure. Loaded with the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the LBM PDU received by the an MP OpCode Demultiplexer (19.2.7) when an LBM is received.

20.28 MP Loopback Responder procedures

The following procedures are defined for the Loopback Responder:

a) ProcessLBM() (20.28.1)
b) xmitLBR() (20.28.2)

20.28.1 ProcessLBM()

Called by the MP Loopback Responder state machine whenever an LBM is received. ProcessLBM() processes the LBM in LBMPDU as follows:

a) If :
   1) the destination_address parameter contains an individual MAC address that does not match the MAC address of the receiving MP and
   2) the MP Loopback Responder state machine does not reside in a PBB-TE or SPBM VID MHF,

   ProcessLBM() discards the LBM and performs no further processing.
b) If the destination_address parameter contains a Group address and the MP Loopback Responder state machine resides in an MHF associated with neither PBB-TE nor SPBM (rather than in a MEP), ProcessLBM() discards the LBM and performs no further processing.
c) If the source_address parameter is a Group, and not an individual MAC address, ProcessLBM() discards the frame and performs no further processing.
d) ProcessLBM() shall process the LBM according to 20.51.4.2, and may validate the LBM according to 20.51.4.3, and discard any frames that fail the validation.
e) If the MP Loopback Responder state machine resides in a PBB-TE MEP and the LBM carries a PBB-TE MIP TLV, ProcessLBM() discards the LBM and performs no further processing.
f) If the MP Loopback Responder state machine resides in a PBB-TE or SPBM VID MHF and:
   1) There is no PBB-TE MIP TLV or
   2) There is a PBB-TE MIP TLV but the address carried in the MIP MAC address field does not match the MAC address of the receiving MIP,

   ProcessLBM() forwards the LBM to the Passive MHF Multiplexer and performs no further processing.
g) Otherwise, ProcessLBM() calls xmitLBR() to generate and transmit an LBR.

20.28.2 xmitLBR()

Called by ProcessLBM() to transmit an LBR. xmitLBR() constructs an LBR from the LBM contained in LBMPDU, and transmits it to the Active SAP using an M_UNITDATA.request as follows:

a) Sets the destination_address parameter to the source_address of the received LBM if the MP is not associated with a PBB-TE MA; otherwise to:
   1) The value of the ESP-DA of the MA's ESP that has the replying MEP's MAC address [item i) in 12.14.7.1.3] in its ESP-SA field, if the MEP is a PBB-TE MEP; or otherwise to
   2) The value carried in the Reverse MAC field contained in the PBB-TE MIP TLV of the received LBM, if this is a group MAC address; otherwise to
   3) The source_address of the received LBM.
b) Sets the source_address parameter to the MAC address of the replying MP if the MP is not a PBB-TE MHF; or otherwise to:
   1) The destination_address of the received LBM if this is an individual MAC address; or otherwise to

2) The value carried in the Reverse MAC field contained in the PBB-TE MIP TLV of the received LBM.

c) If the LBM was received at a PBB-TE MHF and contains a PBB-TE MIP TLV, then the vlan_identifier in the LBR is set to the value in the Reverse VID field; otherwise, the vlan_identifier in the LBR is set to the value of the Primary VID associated with the replying MP [item d) in 12.14.7.1.3, item a) in 12.14.3.2.2, item c) in 12.14.5.3.2].

d) In the case of ECMP with flow filtering, the flow_hash parameter is set to zero and the time_to_live parameter is set to 63.

e) The priority parameter and the drop-eligible parameter are copied from the LBM.

f) Changes the OpCode field (21.4.3) from LBM to LBR.

g) Copies the remainder of the LBM's mac_service_data_unit verbatim to the LBR.

h) If the replying MP is a MEP, increments the LBR transmission counter by 1 [item ad) in 12.14.7.1.3].

20.29 MP Loopback Responder state machine

The MP Loopback Responder state machine implements the functions specified by the state diagram in Figure 20-10, using the variables in 20.27 and the procedures in 20.28. Although the definition of the MP Loopback Responders in 19.2.10 and 19.3.8 requires the instantiation of an MP Loopback Responder state machine in every MP, in practice, the number of MP Loopback Responder state machines implemented in a system cannot be determined from external observation of the system.

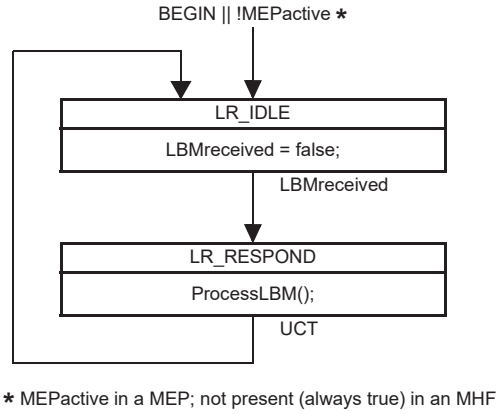

Figure 20-10—MP Loopback Responder state machine

20.30 MEP Loopback Initiator variables

The following variables are local to the MEP Loopback Initiator transmit state machine and the MEP Loopback Initiator receive state machine:

a) LBMsToSend (20.30.1)
b) nextLBMtransID (20.30.2)
c) expectedLBRtransID (20.30.3)
d) LBIactive (20.30.4)
e) xmitReady (20.30.5)
f) LBRreceived (20.30.6)
g) LBRPDU (20.30.7)

20.30.1 LBMsToSend

The integer number of LBMs that the MEP Loopback Initiator transmit state machine is to transmit. Set by a management operation [item c) in 12.14.7.3.2]. Setting this variable to a nonzero value starts transmission of LBMs. LBMsToSend is decremented by 1 by the MEP Loopback Initiator transmit state machine with each transmission.

20.30.2 nextLBMtransID

The value to place in the Loopback Transaction Identifier field of the next LBM transmitted by xmitLBM(). nextLBMtransID is incremented by 1 by the MEP Loopback Initiator transmit state machine with each transmission. This variable is available as a managed object [item x) in 12.14.7.1.3].

20.30.3 expectedLBRtransID

The value expected to be found in the Loopback Transaction Identifier field of the next LBR received by ProcessLBR(). Altered by ProcessLBR() (see 20.33.1).

20.30.4 LBIactive

A Boolean flag indicating whether the MEP Loopback Initiator transmit state machine is (true) or is not (false) actively engaged in a requested operation. Set to true by the MEP Loopback Initiator transmit state machine after LBMsToSend is set to a nonzero value by a management operation. Reset to false by the MEP Loopback Initiator transmit state machine 5 s after the last LBM is transmitted or the last LBR is received, whichever comes later.

20.30.5 xmitReady

A Boolean flag set to true by the Bridge Port to indicate that another LBM can be transmitted. Reset to false by the MEP Loopback Initiator transmit state machine.

20.30.6 LBRreceived

Boolean flag. Set by the MEP Equal OpCode Demultiplexer (19.2.7) when an LBR at the MEP's MD Level is received. Cleared by the MEP Loopback Initiator receive state machine.

20.30.7 LBRPDU

Structure. Loaded with the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the LBR PDU received by the MEP Equal OpCode Demultiplexer (19.2.7) when an LBR at the MEP's MD Level is received.

20.31 MEP Loopback Initiator transmit procedures

The following procedure is local to the MEP Loopback Initiator transmit state machine:

a) xmitLBM() (20.31.1)

20.31.1 xmitLBM()

xmitLBM() is called by the MEP Loopback Initiator transmit state machine. It constructs and transmits an LBM on the Active SAP using an M_UNITDATA.request as follows:

a) Sets the destination_address parameter from the appropriate managed object [item b) in 12.14.7.3.2] or in the case of an SPBM VID MEP [item g) in 12.14.7.3.2]. If the MEP is configured on a PBB-TE MA, the destination_address parameter is set to the MAC address indicated by the value of the ESP-DA field of the MA's ESP that has the MEP's MAC address indicated in its ESP-SA field.
b) Sets the source_address parameter to the MAC address of the MEP [item i) in 12.14.7.1.3].
c) Sets the priority and drop_eligible parameters from the appropriate managed object [item e) in 12.14.7.3.2].
d) In the case of ECMP with flow filtering, the flow_hash parameter is set from the appropriate managed object [item h) in 12.14.7.3.2] and the time_to_live parameter is set to 63.
e) Copies nextLBMtransID (20.30.2) to the Loopback Transaction Identifier field (21.7.3) of the LBM.
f) If the MEP is configured on a PBB-TE MA, constructs a PBB-TE MIP TLV using in the MIP MAC address field the target address parameter from the appropriate managed object [item b) in 12.14.7.3.2] and in the Reverse VID field the parameter [item f) in 12.14.7.3.2]; if the MEP is a root in a point-to-multipoint TESI, the Reverse MAC field is also included in the PBB-TE MIP TLV carrying the ESP-SA value of any of the MA's point-to-point ESPs; if the MEP is a leaf in a point-to-multipoint TESI, the Reverse MAC field carries the ESP-DA of the point-to-multipoint ESP; the PBB-TE MIP TLV is not used if the LBM target address in 12.14.7.3.2 is associated with any of the values in the ESP-DA field of the monitored MA's ESPs.
g) If the MEP is configured on an SPBM VID MA, constructs a PBB-TE MIP TLV using in the MIP MAC address field the target address parameter from the appropriate managed object [item b) in 12.14.7.3.2].
h) Constructs a Data TLV from the appropriate managed object [item d) in 12.14.7.3.2] if and only if that managed object has a nonzero length.
i) As controlled by the managed objects item e) in 12.14.3.1.3, item d) in 12.14.5.1.3, and item d) in 12.14.6.1.3, places a Sender ID TLV (21.5.3), identifying the transmitting system, in the LBM.
j) Increments nextLBMtransID (20.30.2) by 1, wrapping around from $2^{32} - 1$ to 0.

20.32 MEP Loopback Initiator transmit state machine

A MEP creates a single instance of the MEP Loopback Initiator transmit state machine. The MEP Loopback Initiator transmit state machine implements the function specified by the state diagram in Figure 20-11 and the procedures in 20.31. It shares with the MEP Loopback Initiator receive state machine the variable declarations in 20.30.

20.33 MEP Loopback Initiator receive procedures

The following procedure is local to the MEP Loopback Initiator receive state machine:

a) ProcessLBR() (20.33.1)

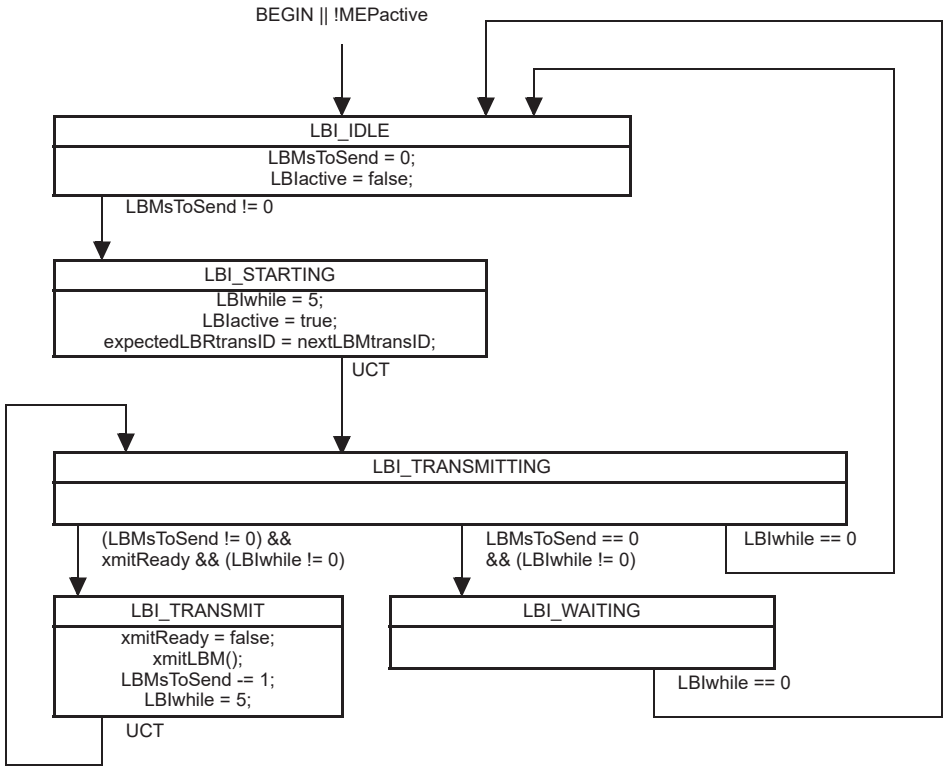

Figure 20-11—MEP Loopback Initiator transmit state machine

20.33.1 ProcessLBR()

Called by the MEP Loopback Initiator receive state machine whenever an LBR is received. ProcessLBR() processes the LBR in LBRPDU as follows:

a) If the I/G bit of the source_address indicates a Group address, or if the destination_address does not match the MAC address of the receiving MP, ProcessLBR() discards the received LBR.

b) ProcessLBR() shall process the LBM according to 20.51.4.2, and may validate the received LBR according to 20.51.4.3, and discard it if invalid.

c) If the LBR is not discarded, and if and only if LBIactive is true, the Loopback Transaction Identifier field of the LBR is compared to expectedLBRtransID:

   1) If the two values are equal, then the number of correct LBRs received [item y) in 12.14.7.1.3] is incremented by 1.

   2) If the two values are unequal, then the value from the received Loopback Transaction Identifier field is copied into expectedLBRtransID, and the number of incorrect LBRs received [item z) in 12.14.7.1.3] is incremented by 1.

   3) Regardless of whether the two values were equal, expectedLBRtransID is then incremented by 1.

d) ProcessLBR() may perform a bit-by-bit comparison of the received LBR against the LBM with the matching Loopback Transaction Identifier, except for the OpCode field, and increment a managed object [item aa) in 12.14.7.1.3] if they do not match.

20.34 MEP Loopback Initiator receive state machine

A MEP creates a single instance of the MEP Loopback Initiator receive state machine. The MEP Loopback Initiator receive state machine implements the function specified by the state diagram in Figure 20-12 and the procedures in 20.33. It shares with the MEP Loopback Initiator transmit state machine the variable declarations in 20.30.

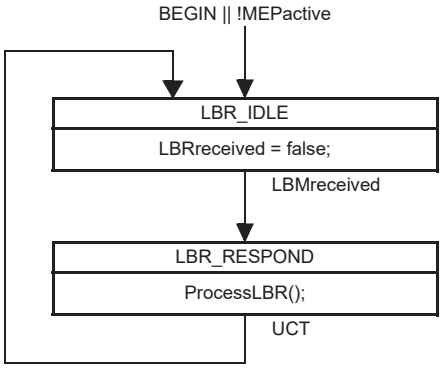

Figure 20-12—MEP Loopback Initiator receive state machine

20.35 MEP Fault Notification Generator variables

The following variables are local to the MEP Fault Notification Generator state machine:

a) fngPriority (20.35.1)
b) fngDefect (20.35.2)
c) fngAlarmTime (20.35.3)
d) fngResetTime (20.35.4)
e) someRMEPCCMdefect (20.35.5)
f) someMACstatusDefect (20.35.6)
g) someRDIdefect (20.35.7)
h) highestDefectPri (20.35.8)
i) highestDefect (20.35.9)

20.35.1 fngPriority

An integer specifying the priority of the last defect reported in a Fault Alarm. fngPriority takes the same values as highestDefectPri (20.35.8).

20.35.2 fngDefect

An enumerated value specifying the last defect reported in a Fault Alarm. fngDefect takes the same values as highestDefect (20.35.9).

20.35.3 fngAlarmTime

The time that one or more defects must be present before a Fault Alarm is issued. Default value 2.5 s. Also a managed object [item l) in 12.14.7.1.3].

20.35.4 fngResetTime

The time, after a Fault Alarm, that no defects must be present before another Fault Alarm is enabled. Default value 10 s. Also a managed object [item m) in 12.14.7.1.3].

20.35.5 someRMEPCCMdefect

A Boolean indicating the aggregate state of the Remote MEP state machines. True indicates that at least one of the Remote MEP state machines is not receiving valid CCMs from its remote MEP, and false that all Remote MEP state machines are receiving valid CCMs. someRMEPCCMdefect is the logical OR of all of the rMEPCCMdefect variables for all of the Remote MEP state machines on this MEP. This variable is readable as a managed object [item q) in 12.14.7.1.3].

20.35.6 someMACstatusDefect

A Boolean indicating that one or more of the remote MEPs is reporting a failure in its Port Status TLV (21.5.4) or Interface Status TLV (21.5.5). It is true either if some remote MEP is reporting that its interface is not isUp (i.e., at least one remote MEP's interface is unavailable), or if all remote MEPs are reporting a Port Status TLV that contains some value other than psUp (i.e., all remote MEPs' Bridge Ports are not forwarding data). It is thus the logical OR of the following two terms:

a) The logical AND, across all remote MEPs, of the rMEPportStatusDefect variable OR
b) The logical OR, across all remote MEPs, of the rMEPinterfaceStatusDefect variable.

This variable is readable as a managed object [item p) in 12.14.7.1.3].

20.35.7 someRDIdefect

A Boolean indicating the aggregate health of the remote MEPs. True indicates that at least one of the Remote MEP state machines is receiving valid CCMs from its remote MEP that has the RDI bit set, and false that no Remote MEP state machines are receiving valid CCMs with the RDI bit set. someRDIdefect is the logical OR of all of the rMEPlastRDI and rMEPlastRDI[i] variables for all of the Remote MEP state machines on this MEP. This variable is readable as a managed object [item o) in 12.14.7.1.3].

20.35.8 highestDefectPri

An integer value indicating the priority of the defect named in the variable highestDefect. See also Table 20-1.

20.35.9 highestDefect

An enumerated value indicating the highest priority defect among the variables xconCCMdefect (20.23.3), errorCCMdefect (20.21.3), someRMEPCCMdefect (20.35.5), someMACstatusDefect (20.35.6), and someRDIdefect (20.35.7), as limited by lowestAlarmPri (20.9.5). This variable is readable as a managed object [item c) in 12.14.7.7.2]. The variables, their priorities, and the enumerated values of highestDefect are shown in Table 20-1.

20.36 MEP Fault Notification Generator procedures

The following procedure is local to the MEP Fault Notification Generator state machine:

a) xmitFaultAlarm() (20.36.1).

20.36.1 xmitFaultAlarm()

Transmits a Fault Alarm (12.14.7.7). The identity of the MEP and the variable fngDefect (20.35.2), specifying the cause of the Fault Alarm, are transmitted in the Fault Alarm PDU. The format and method of transmission of the Fault Alarm is not specified in this standard.

20.37 MEP Fault Notification Generator state machine

A MEP creates a single instance of the MEP Fault Notification Generator state machine. The MEP Fault Notification Generator state machine implements the function specified by the state diagram in Figure 20-13, the variables in 20.35, and the procedure in 20.36. The current state of the MEP Fault Notification Generator state machine is available in a managed object [item f) in 12.14.7.1.3].

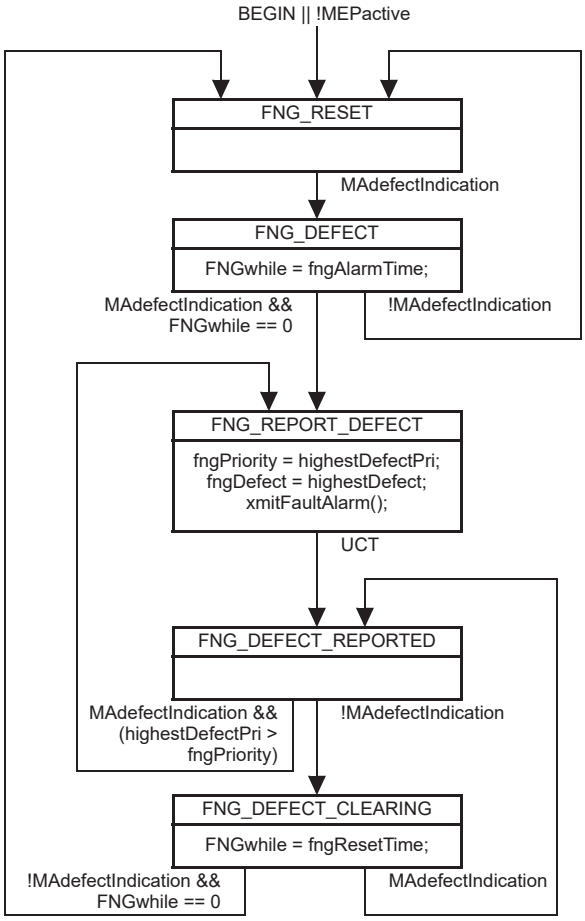

Figure 20-13—MEP Fault Notification Generator state machine

20.38 MEP Mismatch Fault Notification Generator variables

The following variables are local to the MEP Mismatch Fault Notification Generator state machine for a PBB-TE MEP or Infrastructure Segment MEP implementing the Traffic field (21.6.1.4):

a) mfngAllowed (20.38.1)
b) mmdefectIndication (20.38.2)
c) mfngAlarmTime (20.38.3)
d) mfngResetTime (20.38.4)

20.38.1 mfngAllowed

A Boolean indicating the mismatch defect is allowed to generate a Fault Alarm. Its value is configurable as a managed object [item ag) in 12.14.7.1.3].

20.38.2 mmdefectIndication

A Boolean indicating the presence of the mismatch defect that is allowed to generate a Fault Alarm. It corresponds to the logical AND of the variables mfngAllowed (20.38.1), mmCCMdefect (20.25.2), and mmLocdefect (20.25.5).

20.38.3 mfngAlarmTime

The time that one or more defects must be present before a mismatch Fault Alarm is issued. Default value 2.5 s. Also a managed object [item l) in 12.14.7.1.3].

20.38.4 mfngResetTime

The time, after a mismatch Fault Alarm, that no defects must be present before another mismatch Fault Alarm is enabled. Default value 10 s. Also a managed object [item m) in 12.14.7.1.3].

20.39 MEP Mismatch Fault Notification Generator procedures

The following procedure is local to the MEP Mismatch Fault Notification Generator state machine for a PBB-TE MEP or Infrastructure Segment MEP implementing the Traffic field (21.6.1.4):

a) xmitFaultAlarm() (20.36.1)

20.39.1 xmitFaultAlarm()

Transmits a Fault Alarm (12.14.7.7). The identity of the MEP and a value indicating that the cause of the Fault Alarm is a mismatch defect, are transmitted in the Fault Alarm PDU. The format and method of transmission of the Fault Alarm is not specified in this standard.

20.40 MEP Mismatch Fault Notification Generator state machine

A PBB-TE MEP or Infrastructure Segment MEP implementing the Traffic field (21.6.1.4) creates a single instance of the MEP Mismatch Fault Notification Generator state machine. The MEP Mismatch Fault Notification Generator state machine implements the function specified by the state diagram in Figure 20-14, the variables in 20.38, and the procedure in 20.39. The current state of the MEP Mismatch Fault Notification Generator state machine is available in a managed object [item ak) in 12.14.7.1.3].

20.41 MEP Linktrace Initiator variables

The following variables are local to the MEP Linktrace Initiator variables:

a) nextLTMtransID (20.41.1)
b) ltmReplyList (20.41.2)

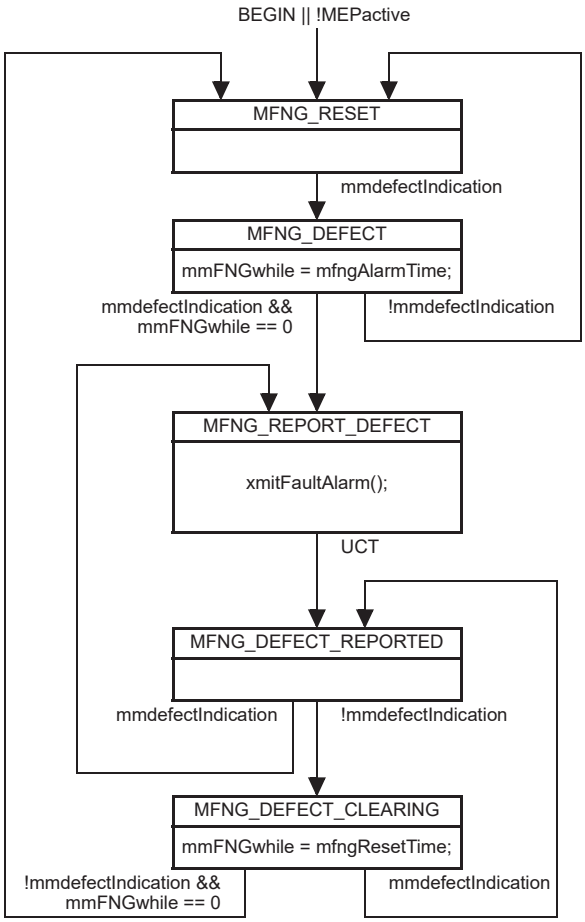

Figure 20-14—MEP Mismatch Fault Notification Generator state machine

20.41.1 nextLTMtransID

The value to place in the LTM Transaction Identifier of the next LTM transmitted by xmitLTM(). nextLTMtransID is incremented by 1 by the MEP Linktrace Initiator variables with each transmission. This variable is also a managed object [item ab) in 12.14.7.1.3].

20.41.2 ltmReplyList

The list of recently-issued LTMs and their corresponding LTRs. An LTM entry, with no attached LTR entries, is added to this list by xmitLTM() each time an LTM is transmitted, and an LTR entry is attached to an LTM entry in this list, by ProcessLTR(), each time an LTR corresponding to an LTM in the list is received. The MEP does not remove any entry from this list before 5 s have elapsed since the transmission of the corresponding LTM, unless the addition of another LTM or LTR entry would exceed the maximum resources allocated for this list. This variable constitutes the Linktrace database for a given MEP and is also a managed object (12.14.7.5.3).

Each LTR entry contains the following variables:

a) ltrFlags (20.41.2.1)
b) ltrReplyTTL (20.41.2.2)
c) ltrLastEgressId (20.41.2.3)
d) ltrNextEgressId (20.41.2.4)
e) ltrRelayAction (20.41.2.5)
f) ltrIngressAction (20.41.2.6)
g) ltrIngressAddress (20.41.2.7)
h) ltrIngressPortIdSubtype (20.41.2.8)
i) ltrIngressPortId (20.41.2.9)
j) ltrEgressAction (20.41.2.10)
k) ltrEgressAddress (20.41.2.11)
l) ltrEgressPortIdSubtype (20.41.2.12)
m) ltrEgressPortId (20.41.2.13)
n) ltrSenderIdTlv (20.41.2.14)
o) ltrOrgSpecTlv (20.41.2.15)

20.41.2.1 ltrFlags

The bit string returned in the Flags field (21.9.1) of the LTR, including the FwdYes and TerminalMEP bits.

20.41.2.2 ltrReplyTTL

The integer value returned in the Reply TTL field (21.9.4) of the LTR.

20.41.2.3 ltrLastEgressId

The octet string returned in the Last Egress Identifier field (21.9.7.1) of the LTR Egress Identifier TLV.

20.41.2.4 ltrNextEgressId

The integer value returned in the Next Egress Identifier field (21.9.7.2) of the LTR Egress Identifier TLV.

20.41.2.5 ltrRelayAction

The enumerated value returned in the Relay Action field (21.9.5) of the LTR. The enumerated values are listed in Table 21-27.

20.41.2.6 ltrIngressAction

The enumerated value returned in the Ingress Action field (21.9.8.1) of the Reply Ingress TLV (21.9.8) of the LTR. The enumerated values are listed in Table 21-30. An enumerated value of 0 indicates that no Reply Ingress TLV was returned in the LTR.

20.41.2.7 ltrIngressAddress

The MAC address of the MP on the Ingress Port. Contents are undefined if no Reply Ingress TLV was returned in the LTR.

20.41.2.8 ltrIngressPortIdSubtype

An enumerated value as specified by IEEE Std 802.1AB, indicating the format of ltrIngressPortId. Contents are undefined if no Reply Ingress TLV was returned in the LTR.

20.41.2.9 ltrIngressPortId

An octet string as specified by IEEE Std 802.1AB, identifying the Ingress Port, in the format identified in ltrIngressPortIdSubtype.

20.41.2.10 ltrEgressAction

The enumerated value returned in the Egress Action field (21.9.9.1) of the Reply Egress TLV (21.9.9) of the LTR. The enumerated values are listed in Table 21-32. A value of 0 indicates that no Reply Egress TLV was returned in the LTR.

20.41.2.11 ltrEgressAddress

The MAC address of the MP on the Egress Port. Contents are undefined if no Reply Egress TLV was returned in the LTR.

20.41.2.12 ltrEgressPortIdSubtype

An enumerated value as specified by IEEE Std 802.1AB, indicating the format of ltrEgressPortId. Contents are undefined if no Reply Ingress TLV was returned in the LTR.

20.41.2.13 ltrEgressPortId

An octet string as specified by IEEE Std 802.1AB, identifying the Egress Port, in the format identified in ltrEgressPortIdSubtype.

20.41.2.14 ltrSenderIdTlv

An octet string identifying the transmitting system, as received in the Sender ID TLV (21.5.3), if one was present in the LTR.

20.41.2.15 ltrOrgSpecTlv

An octet string containing the Organization-Specific TLVs (21.5.2), if any were present in the LTR.

20.42 MEP Linktrace Initiator procedures

The following procedure is local to the MEP Linktrace Initiator:

a) xmitLTM() (20.42.1)

20.42.1 xmitLTM()

xmitLTM() is called whenever the Transmit Linktrace Message management operation (12.14.7.4) is invoked. It constructs and transmits an LTM on the Active SAP, or on the MEP LTI SAP if the operation is invoked on an Up MEP, using an M_UNITDATA.request as follows:

a) Sets the destination_address parameter to the value from Table 8-19 corresponding to the MEP's MD Level. If the MEP is configured on a PBB-TE MA, the destination_address parameter is the MAC address indicated by the value of the ESP-DA field of the MA's ESP that has the MEP's MAC address indicated in its ESP-SA field. If the MEP is configured on an SPBM VID MA, the destination_address parameter is set to the value configured in the LTM management request [item f) in 12.14.7.4.2].
b) Sets the source_address parameter and Original MAC Address field (21.8.5) to the MAC address of the MEP [item i) in 12.14.7.1.3].
c) If the MEP is configured on a PBB-TE MA, constructs a PBB-TE MIP TLV using in the MIP MAC address field a null field and in the Reverse VID field the parameter [item e) in 12.14.7.4.2]; if the

MEP is a root in a point-to-multipoint TESI, the Reverse MAC field is also included in the PBB-TE MIP TLV carrying the ESP-SA value of any of the MA's point-to-point ESPs; if the MEP is a leaf in a point-to-multipoint TESI, the Reverse MAC field carries the ESP-DA of the point-to-multipoint ESP.

d) In the case of ECMP with flow filtering, the flow_hash parameter is set to the value specified in the appropriate managed object [item g) in 12.14.7.4.2] and the time_to_live parameter is set to 63.
e) Sets the priority parameter to the same value as for CCMs [item h) in 12.14.7.1.3].
f) Copies nextLTMtransID [item ab) in 12.14.7.1.3] to the LTM Transaction Identifier field (21.8.3) of the LTM.
g) Sets the LTM Egress Identifier TLV (21.8.8) to a value that is unique among all Bridges in the Management Domain.
h) Sets the Target MAC Address field (21.8.6) from the appropriate managed object [item c) in 12.14.7.4.2].
i) Sets the LTM TTL field (21.8.4) from the appropriate managed object [item d) in 12.14.7.4.2].
j) Sets the UseFDBonly bit of the Flags field (21.8.1) from the appropriate managed object [item b) in 12.14.7.4.2], and sets all other bits of the Flags field to 0.
k) As controlled by the managed objects item e) in 12.14.3.1.3, item d) in 12.14.5.1.3, and item d) in 12.14.6.1.3, places a Sender ID TLV (21.5.3), identifying the transmitting system, in the LTM.
l) Creates a new entry in the ltmReplyList variable (20.41.2) for this LTM, identified by the LTM Transaction Identifier in nextLTMtransID (20.41.1).
m) Increments nextLTMtransID (20.41.1) by 1, wrapping around from $2^{32} - 1$ to 0.

If the addition of this LTM entry would exceed the resources allocated to ltmReplyList, then the oldest LTM entries in ltmReplyList are deleted until sufficient resources are available to hold the new LTM entry.

20.43 MEP Linktrace Initiator receive variables

The following variables are local to the MEP Linktrace Initiator receive state machine:

a) LTRreceived (20.43.1)
b) LTRPDU (20.43.2)

20.43.1 LTRreceived

Boolean flag. Set by the MEP Equal OpCode Demultiplexer (19.2.7) when an LTR at the MEP's MD Level is received. Cleared by the MEP Linktrace Initiator receive state machine.

20.43.2 LTRPDU

Structure. Loaded with the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the LTR PDU received by the MEP Equal OpCode Demultiplexer (19.2.7) when an LTR at the MEP's MD Level is received.

20.44 MEP Linktrace Initiator receive procedures

The following procedure is local to the MEP Linktrace Initiator receive state machine:

a) ProcessLTR() (20.44.1)

20.44.1 ProcessLTR()

The ProcessLTR() procedure is called by the MEP Linktrace Initiator receive state machine whenever an LTR is received, and processes the LTR contained in the LTRPDU variable as follows:

a) If the destination_address of the LTR does not match the MAC address of the MEP, or if the LTR fails the validation criteria of 20.51.4, ProcessLTR() shall discard the LTR without counting it, and no further processing takes place.
b) Otherwise, if the LTR Transaction Identifier field matches an LTM entry in the ltmReplyList variable, then a new LTR entry is attached to that LTM entry, containing the information returned in the LTR.
c) Otherwise, the number of unexpected LTRs received [item ac) in 12.14.7.1.3] is incremented by 1.

If the addition of this LTR entry would exceed the resources allocated to ltmReplyList, then the oldest LTM entries in ltmReplyList (the oldest LTR entries, if only one LTM entry is present) are deleted until sufficient resources are available to hold the new LTR entry.

20.45 MEP Linktrace Initiator receive state machine

One instance of the MEP Linktrace Initiator receive state machine is instantiated by each MEP Linktrace Initiator. The MEP Linktrace Initiator receive state machine implements the function specified by the state diagram in Figure 20-15, the variables in 20.43, and the procedures in 20.44.

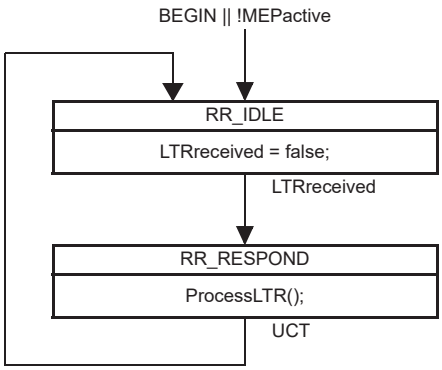

Figure 20-15—MEP Linktrace Initiator receive state machine

20.46 Linktrace Responder variables

The following variables are local to the Linktrace Responder:

a) nPendingLTRs (20.46.1)
b) LTMreceived (20.46.2)
c) LTMPDU (20.46.3)

20.46.1 nPendingLTRs

An integer value used to track the number of LTRs that have been enqueued for transmission by enqueLTR() and not yet transmitted by xmitOldestLTR(). Can be reset to 0 by clearPendingLTRs().

20.46.2 LTMreceived

A Boolean value set when a valid LTM is received and cleared by the LTM Receiver state machine.

20.46.3 LTMPDU

Structure. Loaded with the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the LTM PDU received by the MEP Equal OpCode Demultiplexer (19.2.7) when an LTM at the MEP's MD Level is received.

20.47 LTM Receiver procedures

The following procedures are local to the LTM Receiver state machine:

a) ProcessLTM() (20.47.1)
b) clearPendingLTRs() (20.47.2)
c) ForwardLTM() (20.47.3)
d) enqueLTR() (20.47.4)

20.47.1 ProcessLTM()

Called by the LTM Receiver state machine when an LTM is received and processes the LTM contained in the LTMPDU, making the decision whether to call ForwardLTM() to forward the LTM, and whether to call enqueLTR() to enqueue an LTR for transmission, according to 20.3.2. The received LTM is first validated.

a) ProcessLTM() validates the received LTM according to 20.51.3. If the LTM is invalid, no further validation steps are performed.
b) Otherwise, the LTM TTL field (21.8.4) of the received LTM is examined. If its value is 0, the LTM is invalid, and no further validation steps are performed.
c) Otherwise, if the vlan_identifier identifies an ESP-VID or SPBM VID the LTM is valid, and no further validation steps are performed.
d) Otherwise, if the destination_address parameter of the LTM is a Group address, the LTM is valid, and no further validation steps are performed.
e) Otherwise, if both:
    1) The LTM was received from a Linktrace SAP, and not from the originating Up MEP through its MEP LTI SAP and
    2) The destination_address parameter of the LTM is the individual MAC address of the receiving MP [item i) in 12.14.7.1.3 for a MEP, the MAC address of the Bridge Port for an MHF],

    then the LTM is valid.
f) Otherwise, the LTM is invalid.

20.47.1.1 LTM paths through a Bridge

If the LTM is valid, processing proceeds according to the following subclauses. Otherwise, ProcessLTM() discards the LTM, and no further processing takes place.

Figure 20-16 illustrates a number of (but not all) possible paths taken by an LTM through a Bridge. The gray circles indicate the processing of an LTM and the possible forwarding of a modified copy of the LTM. The LTR path is not shown.

NOTE—All of the MPs shown in Figure 20-16 are at the same MD Level.

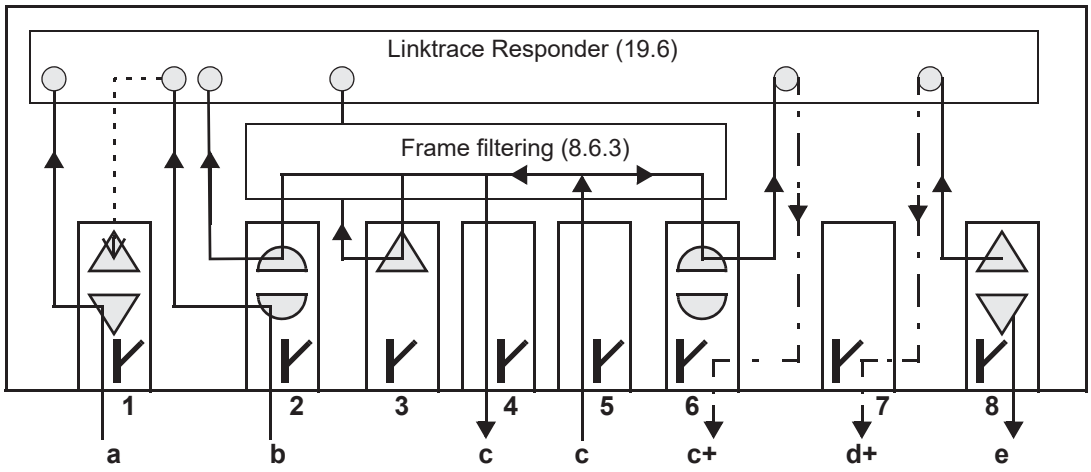

Figure 20-16—Linktrace Responder, MEPs, MHFs, and LOMs

a) An LTM is detected by a Down MEP as it enters Port 1. It is deflected to the Linktrace Responder through the MEP Linktrace SAP.
b) An LTM is detected by an MHF as it enters Port 2. It is deflected to the Linktrace Responder through the MHF Linktrace SAP, which determines that the Target MAC Address would be forwarded out Port 1, on which there is a MEP. The LTM is not actually forwarded to the MEP.
c) An LTM enters on Port 5, which has no MHF, and if it is a multicast, the LTM is distributed to Ports 2, 3, 4, and 6 by the Frame filtering function (8.6.3). The original, unaltered LTM passes out Port 4. The Up MEP in Port 3 and the MHFs in Ports 2 and 6 deliver the LTM to the Linktrace Responder. The Linktrace Responder discards the LTMs received on Port 2 and 3, but forwards an updated version of the LTM through the LOM on Port 6.
d) The Up MEP on Port 8 generates an LTM, which it forwards to the Linktrace Responder. The Linktrace Responder decides to forward an updated version of the LTM through the LOM on Port 7. (The Linktrace Responder might equally well have forwarded it through some other Port's MHF.)
e) The Down MEP on Port 8 generates an LTM and transmits it through its Active SAP to the LAN attached to Port 8.

If an LTM is forwarded, the forwarding takes place immediately. If an LTR is generated in response to the LTM, it is enqueued for later transmission by the LTR Transmitter state machine (20.50).

20.47.1.2 Ingress Port, vlan_identifier, and Egress Port determination

In 20.3.2 and Figure 20-16, item a) through item e) all require ProcessLTM() to determine the Ingress and Egress Ports for this received LTM. The Ingress Port is the Bridge Port on which the LTM entered the Bridge, whether through a MEP, an MHF, or an LOM. In item d)), where an LTM is generated by an Up MEP and passed through a MEP LTI SAP to the Linktrace Responder, the Ingress Port is the Bridge Port of the originating MEP.

If received from an EISS SAP, the vlan_identifier of the received LTM is included in the EM_UNITDATA.indication. If received from an ISS SAP, the vlan_identifier of the received LTM is that configured in the MEP, MHF, or LOM that received the LTM, or if none, is the PVID (IEEE Std 802.1AC) of the Ingress Port.

The Egress Port is the Bridge Port on which a data frame whose destination_address is equal to the Target MAC Address carried in the LTM, or in the case of an MP associated with a PBB-TE MA, the destination_address of the LTM, and whose vlan_identifier matched that of the LTM, would be forwarded. This determination is made in two steps:

a) ProcessLTM() first queries the FDB (8.8). The set of potential transmission ports, normally created by Active topology enforcement (8.6.1), is the set of all Bridge Ports that are both in the active set of the vlan_identifier of the LTM and that are in the Forwarding state for that vlan_identifier, except that the Ingress Port is excluded from the set. The query uses the Target MAC Address field of the LTM as the destination_address of the lookup, the Original MAC Address field of the LTM as the source_address, and the vlan_identifier of the LTM. In the case of an MP associated with a PBB-TE or SPBM VID MA, the query uses the destination_address and the vlan_identifier of the LTM as the corresponding parameters for the lookup. If the MP is associated with ECMP with flow filtering, the query uses the flow_hash parameter in the lookup process, when required. The output from this query is a (perhaps reduced) set of potential transmission ports. If the resultant set contains one and only one Bridge Port, that Bridge Port is the Egress Port, and item b)) is not performed. If the resultant set contains more than one Bridge Port, and the MP is associated with a PBB-TE MA, those Bridge Ports are all Egress Ports, and step b is not performed.

NOTE 1—If there are only two Bridge Ports that are members of the VID's member set, the Ingress Port was one of those two Bridge Ports, and the Ingress Port is not connected to a shared medium, then this step can identify the Egress Port even if the FDB is not used for this vlan_identifier.

NOTE 2—This query cannot produce an Egress Port that is the same as the Ingress Port, since the Ingress Port is not included in the set of potential transmission ports.

b) If the FDB could not produce a unique Egress Port, and the MPs serving the vlan_identifier of the LTM are maintaining a MIP CCM Database, and the UseFDBonly bit of the Flags field of the LTM is 0, then ProcessLTM() queries the MIP CCM Database to see whether the target MAC address and vlan_identifier have been retained in that database. If so, and if the Port number in the MIP CCM Database is not the same as the Ingress Port, that Port number identifies the Egress Port.

It is possible that neither of these two steps are able to determine the Egress Port; when a unique Egress Port cannot be determined, an LTM is never forwarded by MHFs other than PBB-TE MHFs or SPBM VID MHFs. PBB-TE MHFs associated with point-to-multipoint TESIs forward LTMs even if multiple Egress Ports are identified. MHFs associated with SPBM VID MAs forward group addressed LTMs even if multiple Egress Ports are identified.

20.47.1.3 LTM is received by a Down MEP

In case a) in 20.47.1.1, illustrated in Figure 20-16, the LTM is received by a Down MEP, and delivered to the Linktrace Responder through its MEP Linktrace SAP (19.2.14). In this case, ProcessLTM() performs the following steps:

a) If the Target MAC Address carried in the LTM is the MAC address of the receiving MEP, then the LTM has reached its target. ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MEP Linktrace SAP of the receiving Down MEP.
b) Otherwise, if the spanning tree state of the Bridge Port and vlan_identifier of the LTM is not Forwarding, the LTM is discarded and no further processing takes place.
c) Otherwise, the Ingress and Egress Ports are determined according to 20.47.1.2. If a unique Egress Port cannot be determined, then the LTM is discarded, and no further processing takes place.
d) Otherwise, i.e., a unique Egress Port was found, ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the Linktrace SAP through which the LTM was received. The LTM is discarded, and no further processing takes place.

20.47.1.4 LTM is received by a Down MHF or originated by an Up MEP

In case b) in 20.47.1.1, illustrated in Figure 20-16, the LTM is received by a Down MHF. In case d) in 20.47.1.1, illustrated in Figure 20-16, the LTM is originated by an Up MEP. In either case, ProcessLTM() performs the following steps:

a) If the LTM was generated by an Up MEP, item b)) and item c)) are skipped, and processing continues with item d)), as follows.

b) If the Target MAC Address carried in the LTM is the MAC address of the receiving MHF, then the LTM has reached its target. ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the Linktrace SAP through which the LTM was received. The LTM is discarded, and no further processing takes place.

c) Otherwise, if the spanning tree state of the Bridge Port and vlan_identifier of the LTM is not Forwarding, the LTM is discarded and no further processing takes place.

NOTE—This test prevents spurious LTRs from being generated on Backup Ports on a shared medium.

d) Otherwise, the Ingress and Egress Ports are determined according to 20.47.1.2. If an Egress Port cannot be determined, then the LTM is discarded, and no further processing takes place.

e) There are three cases for further processing of the LTM, depending on whether, as it passes through the Egress Port, a frame with the LTM's vlan_identifier would first encounter an Up MEP, an Up MHF, or neither. These described in item f)), item g)), item h)), and item i)), as follows.

f) If an Up MHF would be encountered on the Egress Port, then:

   1) ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MHF Linktrace SAP of the Egress Port's Up MHF.

   2) If the target MAC address carried in the LTM is the Egress Port Up MHF's MAC address, then the LTM is discarded, and no further processing takes place.

   3) Otherwise, if the LTM TTL field equals 0 or 1, the LTM is discarded and no further processing takes place.

   4) Otherwise, ProcessLTM() calls ForwardLTM() (20.47.3) to forward an altered copy of the LTM through the LOM Linktrace SAP of the LOM on the identified Egress Port.

g) If an Up MEP at the MD Level of the LTM would be encountered on the Egress Port, then:

   1) ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MHF Linktrace SAP of the Ingress Port's Down MHF, or the MEP LTI SAP of the Up MEP, that delivered the LTM to the Linktrace Responder.

   2) The LTM is discarded, and no further processing takes place.

h) Otherwise, if an Up MEP higher than the MD Level of the LTM would be encountered on the Egress Port, then the LTM is discarded, and no further processing takes place.

i) If neither an Up MHF, nor an Up MEP at an MD Level higher than or equal to the LTM, would be encountered on the Egress Port, then:

   1) ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MHF Linktrace SAP of the Ingress Port's Down MHF.

   2) If the LTM TTL field equals 0 or 1, the LTM is discarded and no further processing takes place.

   3) Otherwise, ProcessLTM() calls ForwardLTM() (20.47.3) to forward an altered copy of the LTM through the LOM Linktrace SAP of the LOM that a frame with the LTM's vlan_identifier would first encounter when passing out through the identified Egress Port.

20.47.1.5 LTM is received by an Up MEP

In case c) in 20.47.1.1, illustrated in Figure 20-16, an LTM enters a Bridge on a Bridge Port that has no MEP or MHF and therefore only an LOM. The LTM can therefore be received by an Up MEP such as the one on Port 3 of Figure 20-16. Processing of an LTM received on an Up MEP proceeds as follows:

a) If the Target MAC Address carried in the LTM is the MAC address of the receiving MEP, then the LTM has reached its target. ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MEP Linktrace SAP of the receiving Up MEP. The LTM is discarded, and no further processing takes place.
b) Otherwise, the Ingress and Egress Ports are determined according to 20.47.1.2. If the Egress Port cannot be determined, or if the Egress Port is not the Bridge Port on which the receiving MEP is configured, then the LTM is discarded and no further processing takes place.
c) Otherwise, (i.e., the Egress Port is that of the receiving Up MEP) ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MEP Linktrace SAP of the receiving Up MEP. The LTM is then discarded.

20.47.1.6 LTM is received by an Up MHF

In case c) in 20.47.1.1, illustrated in Figure 20-16, an LTM enters a Bridge on a Bridge Port that has no MEP or MHF and therefore only an LOM. The LTM can therefore be received by an Up MHF such as the ones on Port 2 and Port 6 of Figure 20-16. Processing of an LTM received on an Up MHF proceeds as follows:

a) If the Target MAC Address carried in the LTM is the MAC address of the receiving Up MHF (i.e., that of the Bridge Port on which that MHF resides), then the LTM has reached its target. ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MHF Linktrace SAP of the receiving Up MHF. The LTM is discarded, and no further processing takes place.
b) Otherwise, the Ingress and Egress Ports are determined according to 20.47.1.2. If the Egress Port cannot be determined, or if the Egress Port is not the Bridge Port on which the receiving MHF is configured, then the LTM is discarded, and no further processing takes place.
c) Otherwise,
    1) ProcessLTM() calls enqueLTR() (20.47.4) to enqueue an LTR for the MHF Linktrace SAP of the receiving Up MHF.
    2) If the LTM TTL field equals 0 or 1, the LTM is discarded and no further processing takes place.
    3) Otherwise, ProcessLTM() calls ForwardLTM() (20.47.3) to forward an altered copy of the LTM through the MHF Linktrace SAP of the LOM on the same Bridge Port as the Up MHF that received the LTM.

20.47.2 clearPendingLTRs()

Clears the queue of pending LTRs for this MP. Resets nPendingLTRs to 0.

20.47.3 ForwardLTM()

Constructs and transmits a single LTM. Using the original input LTM and the Linktrace Responder SAP through which the LTM (LTR) is to be output, ForwardLTM() performs the following steps:

a) Uses the MAC address of the LOM owning the SAP specified for output as the source_address parameter of the LTM.
b) Uses the destination_address and priority parameters of the input LTM as the destination_address and priority of the forwarded LTM.
c) Sets the drop_eligible parameter of the forwarded LTM to false.

d) Uses the same value for the vlan_identifier parameter for the forwarded LTM that was presented with the received LTM.
e) In the case of ECMP with flow filtering, the flow_hash parameter and the time_to_live parameter of the forwarded LTM are set to values presented with the received LTM.
f) In PBB-TE related MAs, uses the destination_address, source_address, and vlan_identifier of the input LTM and sets the drop_eligible parameter of the forwarded LTM to FALSE.
g) Copies, verbatim, all fields and TLVs, regardless of whether known to the Linktrace Responder, from the input LTM to the forwarded LTM, except that ForwardLTM():
    1) Places in the forwarded LTM TTL field the value from the input LTM TTL field decremented by 1.
    2) Changes the value in the LTM Egress Identifier TLV to identify the forwarding Linktrace Responder.
    3) Deletes the Sender ID TLV (21.5.3), if present in the LTM.
    4) Optionally, places a Sender ID TLV (21.5.3), identifying the forwarding system, in the LTM.
h) Transmits the forwarded LTM on the specified SAP.

20.47.4 enqueLTR()

Constructs and enqueues a single LTR for later transmission by xmitOldestLTR() as follows. Using the input LTM and the Linktrace Responder SAP through which the LTR is to be output, enqueLTR() performs the following steps:

a) Uses the MAC address contained in the LTM's Original MAC Address field as the destination_address of the LTR. If the MP is associated with a PBB-TE MA, the LTR uses as destination_address,
    1) The value carried in the Reverse MAC field, contained in the PBB-TE MIP TLV of the received LTM, if this is a group MAC address; otherwise,
    2) The source_address of the received LTM.
b) Uses the MAC address of the MP owning the SAP specified for output as the source_address of the LTR, if the MP is not a PBB-TE MHF; otherwise, the LTR uses as the source_address:
    1) The value of the destination_address of the received LTM if this is an individual MAC address; otherwise,
    2) The value carried in the Reverse MAC field, contained in the PBB-TE MIP TLV of the received LTM,
c) If the LTR includes a Reply Egress TLV [see the following item r))], uses the Primary VID of the MP on that Egress Port as the vlan_identifier of the LTR, else it uses the Primary VID of the MP on the Ingress Port as the vlan_identifier of the LTR. In PBB-TE related MA's, sets the vlan_identifier parameter as the value carried in the Reverse VID field contained in the PBB-TE MIP TLV of the received LTM.
d) Sets the priority parameter to the same value as for CCMs [item h) in 12.14.7.1.3].
e) In the case of ECMP with flow filtering, the flow_hash parameter is set to zero and the time_to_live parameter is set to 63.
f) Sets the drop_eligible parameter to FALSE.
g) Places its own version in the Version field.
h) If its own version is lower than that of the received LTM, sets all bits and fields in the transmitted PDU that are reserved in its own version, including all bits between the portion of the last header field defined for its own version and the first TLV, to 0.
i) Sets the FwdYes bit of the Flags field to 1 if the LTM was forwarded by the Linktrace Responder, or 0 if not.

j) Sets the TerminalMEP bit of the Flags field to 1 if the MP reported in either the Reply Ingress TLV or the Reply Egress TLV is a MEP, or 0 if not.

k) Copies the Flags field, excepting the FwdYes bit and the TerminalMEP bit, from the LTM to the LTR.

l) Copies the LTM Transaction Identifier field from the LTM to the LTR Transaction Identifier field of the LTR.

m) Copies the LTM Egress Identifier TLV (21.8.8) value from the LTM to the Last Egress Identifier field (21.9.7.1) of the LTR Egress Identifier TLV, or places 0 in that field, if there is no LTM Egress Identifier TLV in the received LTM (see J.4).

n) Sets the Next Egress Identifier field (21.9.7.2) of the LTR Egress Identifier TLV to a value that identifies the forwarding Linktrace Responder (see 21.8.8).

o) Places one less than the value in the LTM TTL field of the LTM in the Reply TTL field of the LTR;

p) Sets the Relay Action field according to Table 21-27.

q) If the LTM was not received by a Down MEP or Down MHF, does not place a Reply Ingress TLV in the LTR; otherwise,

   1) Fills the Ingress Action field of a Reply Ingress TLV (21.9.8) with the appropriate value according to Table 21-30;

   2) Places the receiving MP's MAC address in the Ingress MAC Address field of the Reply Ingress TLV; and

   3) Optionally, fills the remainder of the Reply Ingress TLV with the receiving MP's Port ID information.

r) If the LTM was received by a Down MEP, or if no Egress Port was identified, or if no Up MEP nor Up MHF belonging to the LTM's MA is configured on the Egress Port, does not place a Reply Egress TLV in the LTR; otherwise,

   1) Fills the Egress Action field of a Reply Egress TLV (21.9.9) with the appropriate value according to Table 21-32;

   2) Places the Egress Port's Up MP's MAC address in the Egress MAC Address field of a Reply Egress TLV in the LTM; and

   3) Optionally, fills the remainder of the Reply Egress TLV with Egress Port's Port ID information.

s) As controlled by the managed objects item e) in 12.14.3.1.3, item d) in 12.14.5.1.3, and item d) in 12.14.6.1.3, places a Sender ID TLV (21.5.3), identifying the replying Bridge, in the LTM.

t) Copies, verbatim, all other TLVs in the input LTM to the LTR, except for the Sender ID TLV (21.5.3), which is not copied.

NOTE 1—Forwarding all unknown TLVs in both the LTM and the LTR enables future revisions of this standard, and designers of Organization-Specific TLVs, to add new capabilities.

NOTE 2—The resultant LTR can be larger than the maximum frame size for the media-dependent sublayer on which the LTR is to be transmitted, causing the LTR to be discarded.

u) Increments nPendingLTRs by 1.

20.48 LTM Receiver state machine

One instance of the LTM Receiver state machine is instantiated by Bridge's Linktrace Responder. The LTM Receiver state machine implements the function specified by the state diagram in Figure 20-17, the variables in 20.46, and the procedures in 20.47.

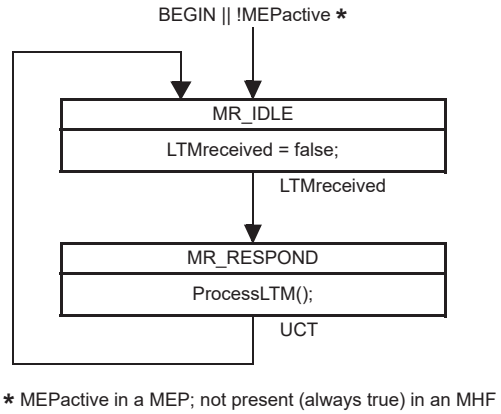

Figure 20-17—LTM Receiver state machine

20.49 LTR Transmitter procedure

The following procedure is local to the LTR Transmitter state machine:

a) xmitOldestLTR() (20.49.1)

20.49.1 xmitOldestLTR()

If and only if nPendingLTRs is nonzero, dequeues a single LTR and transmits it, and decrements nPendingLTRs by 1.

20.50 LTR Transmitter state machine

One instance of the LTR Transmitter state machine is instantiated by Bridge's Linktrace Responder. The LTR Transmitter state machine implements the function specified by the state diagram in Figure 20-18, the variables in 20.46, and the procedures in 20.47.

This state machine implements the requirement of (20.3.2) to wait a random time interval after receiving an LTM before transmitting an LTR by means of a free running 1 s timer, the expiry of which triggers all LTR transmissions. This method avoids the need to create and manage a timer for every LTM received. Any other implementation that meets the requirements of 20.3.2 can be used in place of this state machine.

20.51 CFM PDU validation and versioning

The purpose of this subclause is to state specific goals to be achieved by CFM with respect to the relationship of this and future versions of this standard, and to define the procedures necessary to meet those goals.

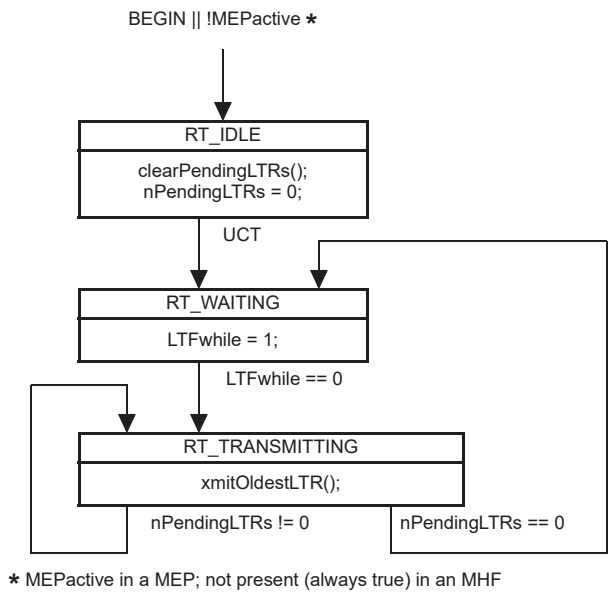

Figure 20-18—LTR Transmitter state machine

20.51.1 Goals of CFM PDU versioning

The goals of CFM with respect to the relationship of this and future versions of this standard are to ensure that:

a) Implementations of this standard will interoperate with implementations of future versions of this standard.
b) Implementers will be able to offer proprietary, nonstandard extensions to this standard with enhanced functionality.
c) Conformant but extended implementations of this standard will not restrict the ability of future versions of this standard to extend the standard functionality.

20.51.2 PDU transmission

In order to ensure that future versions of CFM will be compatible with implementations of this standard, certain requirements are placed on transmitted CFM PDUs:

a) The fixed header fields shall be transmitted exactly as specified in this standard.
b) All bits defined as “reserved” in this standard, e.g., unused bits in the Flags field, shall be transmitted as 0.
c) Additional fields shall not be added to the fixed header specified in this standard.
d) Code points reserved in this standard, or in ITU-T G.8013/Y.1731, e.g., additional values for the OpCode field in the fixed header (Table 21-3), the Type field in a TLV (Table 21-5), or the reserved values in Table 21-18 for the Maintenance Domain Name Format, shall not be transmitted in any CFM PDU.
e) Additional fields shall not be added to any TLV specified in this standard.

Organization-Specific TLVs can be defined by any organization possessing an OUI or a CID, and may be transmitted by an implementation conformant to this standard.

NOTE—The preceding is not an exhaustive list of the restrictions on the transmission of CFM PDUs; it is only a list of the specifications that are most important to future compatibility.

20.51.3 PDU validation

CFM PDUs that fail certain specified tests are discarded by MPs. This requirement is described here as a two-pass processing algorithm, first a Validation Pass, and then an Execution Pass. The Validation Pass is performed first. If and only if it succeeds, the Execution Pass is performed. This description does not preclude other algorithms. For example, an MP could process a CFM PDU in one pass, building a tentative list of changes to the affected state machines and databases, and commit the changes only after the processing has succeeded. However, the behavior of such an implementation shall be indistinguishable, in terms of externally observable behavior (i.e., Management Objects and protocol frames) from the two-pass algorithm described in this subclause.

20.51.4 Validation pass

During the Validation pass, no changes are made to any CFM database other than the updating of certain management counter variables. No protocol state machines are affected, and no changes are made to any CFM PDUs that can be transmitted by the receiving MP. The description of the Validation pass is split into three parts:

a) Operations required of an MP Level Demultiplexer (20.51.4.1)
b) Operations required of all MP components when performing the Validation pass (20.51.4.2)
c) Operations that are required of some MP components, and optional for others (20.51.4.3)

20.51.4.1 Validation pass operations required of an MP Level Demultiplexer

If the following test fails, the receiving MP Level Demultiplexer (19.2.6) shall consider the CFM PDU invalid and discard it:

a) The length of the mac_service_data_unit is long enough to contain a complete MD Level field.

20.51.4.2 Validation pass operations required of MP components

All bits declared “reserved” in this standard, e.g., unused bits in the Flags field, shall be ignored by the receiving MP.

The receiving MP processes the CFM PDU in accordance with the numerically lower of 1) the Version field in the CFM PDU and 2) the highest Version number known to the receiving implementation. That is, a Version 1 implementation receiving a Version 0 CFM PDU processes it according to Version 0 of this standard, and it processes a Version 2 CFM PDU according to Version 1. The IEEE 802.1 Working Group places the imposition on future versions of this standard that all earlier version implementations can process their CFM PDU properly.

As an example of the use of this rule, if a new Flags field bit is defined in Versions 2 and 3, then a Version 3 implementation receiving a Version 1 CFM PDU will ignore that bit, even though the bit is defined in both Version 2 and Version 3, and even though the bit is actually set.

NOTE 1—One effect of this rule is that an implementation conformant to this Version of this standard, Version 0, ignores the Version field in a received CFM PDU.

The following criteria shall not be used by a CFM entity to validate a received CFM PDU:

a) The fixed header can be longer than the length specified by the version of this standard indicated by the CFM PDU’s Version field.
b) Bits can be set in reserved bits of the Flags field.
c) A TLV can have a Type field not specified by this standard.

d) A TLV's Length field can be larger than the value (if any) specified in this standard. (This allows TLVs to be extended in future Versions.)

e) Either the First TLV Offset field, or the Length field of the last TLV, in the CFM PDU, can indicate a position for the first (next) TLV that coincides with the end of the mac_service_data_unit containing the CFM PDU. That is, the End TLV can be missing from the CFM PDU if the frame is longer than or equal to the minimum frame size for the media-dependent MAC sublayer.

NOTE 2—These latter criteria cannot be used by a CFM entity to validate a received CFM PDU. This helps to ensure that the CFM PDUs transmitted by future versions of this standard will be considered valid by implementations of the current version (0) of this standard. These criteria can, however, be used by test equipment in order to test the conformance of a system to this standard, e.g., to the rules in 20.51.2.

20.51.4.3 Validation pass operations required of some receiving MP components

The following Validation pass tests are required of some receiving MP components, and are optional for other MP components, as specified in other subclauses. If performed, and if any test fails, the receiving System shall consider the CFM PDU invalid and discard it.

a) The fixed header length, as determined by the First TLV Offset field (21.4.5), is not shorter than the length specified by the version selected according to 20.51.4.2.

b) The fixed-length header does not run over the end of the mac_service_data_unit.

c) A TLV Length field does not run over the end of the mac_service_data_unit.

d) A TLV Length field does not indicate a length that is shorter than the minimum length for that TLV as specified by the Version field of the CFM PDU.

e) Every header field and TLV in the CFM PDU meets the validity criteria specified in the header field and TLV definitions in Clause 21 (see the Validation Test headings in that clause).

20.51.5 Execution pass

The CFM PDU is processed in the Execution Pass. Changes to the CFM databases can be made, the state machines can change states, and the contents of future CFM PDUs can be affected by these changes. The receiving MP:

a) Processes the CFM PDU in accordance with the numerically lower of 1) the Version field in the CFM PDU; and 2) the highest Version number known to the receiving implementation.

b) Processes only those fields in the fixed header portion of the CFM PDU that are defined in the selected Version of the standard, and ignores any extra octets in the fixed header, if the fixed header is longer than the length specified by the selected Version.

c) Ignores any TLV with a Type field not specified by the selected Version.

d) Does not process any part of the CFM PDU following the End TLV (the lack of an End TLV is not an error).

e) Ignores any octets following those specified by the selected Version, if any TLV's Length field is larger than the value (if any) specified the selected Version.

f) Ignores all bits undefined in this standard, e.g., unused bits in the Flags field.

Unlike the loss of ST BPDUs, the loss of CFM PDUs cannot completely disrupt the function of the network. Also, unlike other control protocols such as the IEEE 802.3 Slow Protocols, CFM PDUs can be presented at an arbitrarily high rate. Therefore, a Bridge shall ensure that receiving CFM PDUs on all Bridge Ports at the maximum possible rate supported by the MAC Services underlying those ports shall not significantly increase the probability of the failure of the Bridge to maintain loop-free forwarding paths in the bridged network. Rather, the Bridge's CPU can be protected against excess CFM PDUs in a similar manner as for other potential Denial of Service attacks.

20.51.6 Future extensions

It is expected that future versions of this protocol will utilize the above versioning rules in order to extend the CFM PDU format in any number of ways, including perhaps:

a) Adding new fields to the header by increasing the minimum size of the First TLV Offset field, and placing the new header fields after the First TLV Offset field in the Version 0 header.
b) Adding new TLVs and extending the lengths of existing TLVs with new fields.
c) Adding a new TLV, that is the first TLV to be processed, by renaming the First TLV Offset field to the "First Version 0 TLV Position," adding a new "Version X Header Length" field following the fields in the Version 0 header, and inserting one or more Version X TLVs just ahead of the first required Version 0 TLV.
d) Adding new information, perhaps fixed-length information, that is required to follow the End TLV specified in Version 0.

Other methods for extending the CFM PDU format are certainly possible. It is therefore critical that Version 0 implementations adhere to the versioning requirements of this clause.

NOTE—The extension options discussed in this clause are reserved for use by future versions of this standard. Each one is a violation of 20.51.2, 20.51.4, and/or 20.51.5. The Organization-Specific TLV is the only available compliant extension to this standard.

20.52 PDU identification

A received CFM PDU is associated with a particular MP. Every data frame, including one carrying a CFM PDU, has some means, either explicit or implicit, by which that frame can be associated by the receiver with a particular service instance. In a Bridge that is not VLAN aware, there is only one service instance. In a VLAN Bridge, the vlan_identifier (6.8) identifies the service instance. The means by which the appropriate receiving MP for processing a received CFM PDU is selected are as follows:

a) The direction (PHY side or MAC Relay Entity side) from which the CFM PDU was received.
b) The implicit or explicit association of the frame with a particular service instance (the vlan_identifier).
c) The MD Level field in the CFM Header.

Once the frame containing the CFM PDU has been delivered to the appropriate entity within an MP, the destination_address can be used to decide whether the CFM PDU is to be processed or discarded, as specified in the description of each entity.

The MAID and/or Maintenance association Endpoint Identifier field is not used to identify the receiving MP. Thus, if the Individual MP address model (see J.6) is used by a particular Bridge, and each MP uses its Bridge Port's individual MAC address, then the VID, MD Level, and flow direction uniquely identify the receiving MEP. If the Shared MP address model is used by a Bridge, so that Up MPs in the Bridge can share a MAC address, then the specific Bridge Port that is the target of an LBM can be genuinely ambiguous. This ambiguity allows the designer to trade the value of detailed information against cost of obtaining that information.

20.53 Use of transaction IDs and sequence numbers

Each CCM, LBM, and LTM has a field (21.6.3, 21.7.3, and 21.8.3) that is incremented for each PDU transmitted of each type, so that consecutively transmitted PDUs are in numerical order. The variables that control these fields are CCIsentCCMs (20.10.2, for CCM), nextLBMtransID (20.30.2, for LBM), and nextLTMtransID (20.41.1, for LTM).

In theory, every MEP in a Bridge has a CCIsentCCMs variable, a nextLBMtransID variable, and a nextLTMtransID variable, independently from every other MEP. Therefore, any number of MEPs in a single Bridge could be transmitting independent streams of LBMs and LTMs as long as they have different MAC addresses. (If they had the same MAC address, they could not tell each others' LBRs and LTRs apart.)

In practice, there can be fewer instances of these variables and their corresponding state machines than one each per MEP. The managed objects in Clause 12, particularly the definitions of the MEP's LBR counters [item y) in 12.14.7.1.3 and item z) in 12.14.7.1.3] and the responses permitted to the Transmit Loopback Messages command (12.14.7.3.3), are specified so that any number of MEP Loopback Initiator transmit state machines, from one to the number of MEPs, can be implemented. Each state machine can increment its own nextLBMtransID variable to determine the next transmitted Loopback Transaction Identifier field. Similarly, the allowed responses to the Transmit Linktrace Message command (12.14.7.4.3) provide the same latitude for the number of nextLTMtransID variables implemented. The resources for transmitting LTMs or streams of LBMs can then be used serially, rather than simultaneously, by different MEPs in the same Bridge.

On the other hand, every MEP that is incrementing its CCIsentCCMs variable has its own instance of that variable, and thus its own MEP Continuity Check Initiator state machine, because the Remote MEP state machines receiving those CCMs are tracking each MEP's sequence of CCMs independently. A MEP can also transmit 0 in every CCM's Sequence Number field.

21. Encoding of CFM PDUs

This clause specifies the method of encoding CFM PDUs. The specifications include the following:

a) Format used to encapsulate or decapsulate a CFM PDU in a frame (21.2).
b) Format of the Common CFM Header, used in all CFM PDUs (21.4).
c) Format used for all Type, Length, Value (TLV) information elements that can be included in CFM PDUs (21.5).
d) Formats of the Continuity Check Message (CCM, 21.6), the Loopback Message and Loopback Reply (LBM and LBR, 21.7), the Linktrace Message (LTM, 21.8), Linktrace Reply (LTR, 21.9), Send Frame Message (SFM, 29.4.3), and the Reflected Frame Message (RFM, 29.4.2).

NOTE—Clause 18 introduces the principles of CFM operation and the network architectural concepts that support it. Clause 19 breaks down the CFM protocol entities into their components. Clause 20 specifies the protocols operated by the components of each MP. The use of CFM within systems and networks is further described in Clause 22.

21.1 Structure, representation, and encoding

All CFM PDUs shall contain an integral number of octets.

The octets in a CFM PDU are numbered starting from 1 and increasing in the order they are put into the MSDU that accompanies a request to or indication from the instance of the MAC Internal Sublayer Service (ISS or EISS) used by a CFM entity.

The bits in an octet are numbered from 1 to 8 in order of increasing bit significance, where 1 is the LSB in the octet.

Where octets and bits within a CFM PDU are represented using a diagram, octets shown higher on the page than subsequent octets and octets shown to the left of subsequent octets at the same height on the page are lower numbered; bits shown to the left of other bits within the same octet are higher numbered.

Where two or more consecutive octets are represented as hexadecimal values, lower numbered octet(s) are shown to the left and each octet following the first is preceded by a hyphen, e.g., 01-80-C2-00-00-00.

When consecutive octets are used to encode a binary number, the lower octet number has the more significant value. When consecutive bits within an octet are used to encode a binary number, the higher bit number has the most significant value. When bits within consecutive octets are used to encode a binary number, the lower octet number composes the more significant bits of the number. A flag is encoded as a single bit, and is set (True) if the bit takes the value 1, and clear (False) otherwise. The remaining bits within the octet can be used to encode other protocol fields.

21.2 CFM encapsulation

The means for identifying CFM PDUs consists of two octets containing the EtherType value shown (in hexadecimal notation) in Table 21-1.

Table 21-1—CFM PDU Encapsulation EtherType

Name	Value
IEEE 802.1Q CFM PDU Encapsulation EtherType	89-02

21.3 CFM request and indication parameters

21.3.1 destination_address parameter

There are three classes of CFM PDUs in terms of the CFM entities to which they are addressed:

a) Those addressed to all MEPs in a service instance (CCM).
b) Those addressed to the set of MPs immediately adjacent to the transmitting MP, at a certain MD Level, in a service instance (LTM).
c) Those addressed to a single, specific MP (LBM, LBR, LTR).

Frames carrying CFM PDUs belonging to two different MAs, but at the same MD Level, are distinguished from each other in the same manner as data frames are distinguished from each other in the corresponding service instances monitored by those MAs.

In a VLAN Bridge, it is the VID that distinguishes service instances. CCMs monitoring a service instance distinguished by its VID use the group MAC addresses listed in Table 8-18 as the destination_address. LTMs monitoring a VID-distinguished service instance use those shown in Table 8-19. All but the last three bits of the destination_address are fixed by the OpCode, either CCM or LTM. As shown in these two tables, the last three bits of the destination_address match the MD Level field of the CFM PDU Header. CFM PDUs belonging to MAs monitoring service instances distinguished by their I-SID use the same set of destination addresses as those belonging to MAs monitoring VLAN service instances. MAs monitoring TESIs are distinguished from MAs monitoring VLAN services by the vlan_identifier parameters and from each other by the 3-tuples <ESP-DA, ESP-SA, ESP-VID> of their ESPs. CFM PDUs belonging to PBB-TE MAs use the MAC address identified in the ESP-DA fields of their ESP identifiers.

21.3.2 source_address parameter

The individual MAC address of the MP transmitting the PDU. This is the MAC address of the transmitting MP. An MP's MAC address is not necessarily unique; MPs configured on the same Bridge Port can share the same MAC address. The principles used to allocate Organization Unique Identifiers (OUIs) required that universally unique MAC addresses (those with the U/L bit = 0, see 8.2 of IEEE Std 802-2014 [B5]) not be used to create MP MAC addresses separately from a physical instance of an IEEE 802 MAC. See J.6 for a discussion of possible assignments of MAC addresses to MPs.

Validation Test: The source_address parameter contains an Individual, and not a Group, MAC address.

21.4 Common CFM Header

The format of a CFM PDU is shown in Table 21-2. A CFM PDU is identified by the encapsulation described in 21.2. Octets 1 through 4, including the MD Level, Version, OpCode, Flags, and First TLV Offset fields, constitute the Common CFM Header.

21.4.1 MD Level

(most significant 3 bits) Integer identifying the Maintenance Domain Level (MD Level) of the frame. Higher numbers correspond to higher MAs, those with the greatest physical reach, with the highest values for customers' CFM frames. Lower numbers correspond to lower MAs, those with more limited physical reach, with the lowest values for single Bridges or physical links.

21.4.2 Version

(least significant 5 bits) The protocol version number, always 0. Ignored on receipt.

Table 21-2—Common CFM Header format

Field	Octet
MD Level	1 (high-order 3 bits)
Version	1 (low-order 5 bits)
OpCode	2
Flags	3
First TLV Offset	4
Varies with value of OpCode	5
End TLV (0)	First TLV Offset + 5

21.4.3 OpCode

(1 octet) The OpCode field specifies the format and meaning of the remainder of the CFM PDU. Certain values of the OpCode field are reserved for allocation by IEEE 802.1 and/or other organizations. The values for the various CFM PDU types are shown in Table 21-3. When assigning new OpCode values, pairs of CFM PDUs that operate in stimulus-response fashion, such as the LBM/LBR or the LTM/LTR pairs, will use even/odd pairs of values such that the odd (numerically larger) of the two values is the stimulus, and the even (numerically smaller) the response.

Table 21-3—OpCode Field range assignments

CFM PDU or organization	OpCode range
Reserved for IEEE Std 802.1	0
Continuity Check Message (CCM)	1
Loopback Reply (LBR)	2
Loopback Message (LBM)	3
Linktrace Reply (LTR)	4
Linktrace Message (LTM)	5
Reflected Frame Message (RFM)	6
Send Frame Message (SFM)	7
Reserved for IEEE Std 802.1Q	8–31
Defined by ITU-T G.8013/Y.1731	32–63
Reserved for IETF (RFC 7319 [B44])	64–95
Reserved for IEEE Std 802.1	96–255

21.4.4 Flags

(1 octet) The use of the Flags field is defined separately for each OpCode.

21.4.5 First TLV Offset

(1 octet) The offset, starting from the first octet following the First TLV Offset field, up to the first TLV in the CFM PDU. The value of the First TLV Offset field shall be transmitted as indicated in the specification for each of the OpCode field values, as follows (21.6.2, 21.7.2, 21.8.2, and 21.9.2).

21.5 TLV format

TLV stands for *Type, Length, Value* and denotes a method of encoding variable-length and/or optional information in a PDU. TLVs are not aligned to any particular word or octet boundary. TLVs follow each other with no padding between TLVs.

21.5.1 General format for CFM TLVs

The TLV format is shown in Table 21-4.

Table 21-4—TLV format

Field	Octet
Type	1
Length	2–3
(Value)	4

21.5.1.1 Type

(1 octet) Required. If 0, no Length or Value fields follow. If not 0, at least the Length field follows the Type field. The Type field is encoded as shown in Table 21-5.

21.5.1.2 Length

(2 octets) Required if the Type field is not 0. Not present if the Type field is 0. The 16 bits of the Length field indicate the size, in octets, of the Value field. 0 in the Length field indicates that there is no Value field.

21.5.1.3 Value

(Length specified by the Length field) Optional. Not present if the Type field is 0 or if Length field is 0.

21.5.2 Organization-Specific TLV

Type = 31. Any organization can define TLVs for use in CFM. The format for such TLVs is shown in Table 21-6. The “OUI/CID” is an organizationally unique identifier or a Company ID, obtainable from IEEE.[36] The Subtype is required, so that an additional OUI/CID will not be required if more Organization-Specific TLV are required by an owner of an OUI/CID.

[36] Interested applicants should contact the IEEE Standards Department of The Institute of Electrical and Electronics Engineers (https://standards.ieee.org/regauth/index.html).

Table 21-5—Type Field values

TLV or organization	Type field
End TLV	0
Sender ID TLV	1
Port Status TLV	2
Data TLV	3
Interface Status TLV	4
Reply Ingress TLV	5
Reply Egress TLV	6
LTM Egress Identifier TLV	7
LTR Egress Identifier TLV	8
PBB-TE MIP TLV	9
Data Part 1 TLV (29.3.3.2)	10
Data Part 2 TLV (29.3.3.2)	11
Truncated Data TLV (29.3.3.2)	12
Reserved for IEEE Std 802.1Q	13–30
Organization-Specific TLV	31
Defined by ITU-T G.8013/Y.1731	32–63
Reserved for IETF (RFC 7319 [B44])	64–95
Reserved for IEEE Std 802.1	96–255

Table 21-6—Organization-Specific TLV format

Field	Octet
Type = 31	1
Length	2–3
OUI/CID	4–6
Subtype	7
Value (optional)	8 – (Length + 3)

This TLV category is provided to allow different organizations, such as IEEE 802.1, IEEE 802.3, ITU-T, as well as individual software and equipment vendors, to define TLVs that advertise information to remote entities attached to the same media, subject to the following restrictions:

a) Information transmitted in an Organization-Specific TLV shall not require the recipient to violate any requirement in this standard.
b) Information transmitted in one Organization-Specific TLV shall not be used to provide a means for sending messages that are larger than would fit within a single CFM PDU.
c) Organization-Specific TLVs shall conform to 20.51.

21.5.3 Sender ID TLV

Type = 1. Identifies the Bridge on which the transmitting MP is configured and may also include a management address for that Bridge. The allowed values are those contained in the Chassis ID TLV and Management Address TLV in IEEE Std 802.1AB, modified to fit into a CFM TLV, as shown in Table 21-7. Whether the Sender ID TLV is transmitted, and what information is included in the TLV, are controlled by managed objects [item e) in 12.14.3.1.3, item d) in 12.14.5.1.3, item d) in 12.14.6.1.3].

Table 21-7—Sender ID TLV format

Field	Octet
Type = 1	1
Length	2–3
Chassis ID Length	4
Chassis ID Subtype	5
Chassis ID	6 – (Chassis ID Length + 5)
Management Address Domain Length	(Chassis ID Length + 6)
Management Address Domain	(Chassis ID Length + 7) – (Chassis ID Length + Management Address Domain Length + 6)
Management Address Length	(Chassis ID Length + Management Address Domain Length + 7)
Management Address	(Chassis ID Length + Management Address Domain Length + 8) – (Length + 3)

Validation Test: The Length field is large enough to contain all of the fields indicated as being present by the Chassis ID Length, Management Address Domain Length, and/or Management Address Length fields.

21.5.3.1 Chassis ID Length

(1 octet) The length, in octets, of the Chassis ID field. 0 if no Chassis ID is specified. Always present.

Validation Test: The Chassis ID Length field either is 0, or is less than (TLV Length field value – 1).

21.5.3.2 Chassis ID Subtype

(1 octet) The **chassis ID subtype**, as specified by IEEE Std 802.1AB, identifying the type of the component referenced by the Chassis ID field. Not present if the Chassis ID Length field contains 0.

21.5.3.3 Chassis ID

(Length specified by the Chassis ID Length field) Identifies the chassis. Specified by IEEE Std 802.1AB. Not present if the Chassis ID Length field contains 0.

21.5.3.4 Management Address Domain Length

(1 octet) The Management Address Domain Length field contains the length, in octets, of the Management Address Domain field. If 0, or if the TLV's Length field indicates that the Management Address Domain Length field is not present, then the Management Address Domain, Management Address Length, and Management Address fields are not present.

21.5.3.5 Management Address Domain

(Length specified by the Management Address Domain Length field) The Management Address Domain field specifies the format and type of the contents of the Management Address field, as well as a management mechanism. The format of the Management Address Domain field shall be that of an Object Identifier (OID), as specified by section 8.19 in ITU-T X.690 (2002). The OID references a TDomain (IETF RFC 2579). Standard values that are useful for the Management Address Domain field include, but are not limited to,

— transportDomainUdpIpv4, indicating Simple Network Management Protocol (SNMP) over User Datagram Protocol (UDP) over IPv4 (IETF RFC 3419).

— transportDomainUdpIpv6, indicating SNMP over UDP over IPv6 (IETF RFC 3419).

— snmpIeee802Domain, indicating SNMP over the MAC Service (IETF RFC 4789).

This field is not present if the Management Address Domain Length field is not present or contains a 0.

21.5.3.6 Management Address Length

(1 octet) The length, in octets, of the Management Address field. This field is not present if the Management Address Domain Length field is not present or contains a 0.

21.5.3.7 Management Address

(Length specified by the Management Address Length field) Identifies a TransportDomain (IETF RFC 3419, IETF RFC 4789) through which the Bridge in which the transmitting MP is configured can be managed. The format of the Management Address field is specified by the MIB module defining the TransportDomain. This field is not present if the Management Address Domain Length field is not present or contains a 0, or if the Management Address Length field is not present or contains a 0.

NOTE—The contents of the Management Address Domain and Management Address are defined in terms of MIB modules. Therefore, a published MIB module is required in order to define a specific valued that can be used in the Management Address Domain field. However, the use of Management Address Domain field by a system does not require that the system be manageable via SNMP; the published MIB module could define, for example, a TransportDomain for a proprietary Command Line Interpreter over ITU-T X.25 [B50].

21.5.4 Port Status TLV

Type = 2. The Port Status TLV indicates the ability of the Bridge Port on which the transmitting MEP resides to pass ordinary data, regardless of the status of the MAC. The value of this TLV is driven by the MEP variable enableRmepDefect (20.9.2), as shown in Table 21-9. The format of this TLV is shown in Table 21-8. Any change in the Port Status TLV's value triggers one extra transmission of that Bridge Port's MEPs' CCMs.

Table 21-8—Port Status TLV format

Field	Octet
Type = 2	1
Length	2–3
See Table 21-9	4

Validation Test: The Port Status TLV contains one of the values listed in Table 21-9.

Table 21-9—Port Status TLV values

mnemonic	Ordinary data passing freely through the Port	value
psBlocked	No: enableRmepDefect = false	1
psUp	Yes: enableRmepDefect = true	2

A MEP that is configured in a Bridge in a position that is not associated with a single value for the Port State and VID member set, e.g., a MEP in position 5 in Figure 22-9, on a Bridge running multiple spanning tree instances via MSTP, shall not transmit the Port Status TLV.

21.5.5 Interface Status TLV

Type = 4. The Interface Status TLV indicates the status of the interface on which the MEP transmitting the CCM is configured (which is not necessarily the interface on which it resides, see J.6), or the next lower interface in the IETF RFC 2863 IF-MIB. The format of this TLV is shown in Table 21-10. The enumerated values are shown in Table 21-11. These values correspond to the values for ifOperStatus in IETF RFC 2863.

Table 21-10—Interface Status TLV format

Field	Octet
Type = 4	1
Length	2–3
See Table 21-11	4

Validation Test: The Interface Status TLV field contains one of the values listed in Table 21-11.

Table 21-11— Interface Status TLV values

mnemonic	Interface Status (IETF RFC 2863 ifOperStatus)	value
isUp	up	1
isDown	down	2
isTesting	testing	3
isUnknown	unknown	4
isDormant	dormant	5
isNotPresent	notPresent	6
isLowerLayerDown	lowerLayerDown	7

21.5.6 Data TLV

Type = 3. Zero or more octets of arbitrary data. Serves several purposes, including reflected data frame in RFM, to be decapsulated data in SFM, the transmission of different frame sizes to test Maximum Service Data Unit Size capabilities and the testing for data-specific error dependencies. The Data TLV may be included in the LBM and the LBR, the RFM, and the SFM, but not in any other CFM PDU. The contents of the Data TLV shall not be examined or interpreted by the receiver of any CFM PDU except an LBR. The format of the Data TLV is shown in Table 21-12.

Table 21-12—Data TLV format

Field	Octet
Type = 3	1
Length	2–3
Data	4 – (Length + 3)

21.5.7 End TLV

Required. Type = 0. Length and Value fields are not present. The End TLV is the last TLV in the CFM PDU. (Lack of the End TLV does not invalidate a received CFM PDU, but certain cases where frames receive extra headers, e.g., MACsec or additional VLAN tags, can cause errors if it is not present.) The format of the End TLV is shown in Table 21-13.

Table 21-13—End TLV format

Field	Octet
Type = 0	1

21.6 CCM format

The format of the CCM is shown in Table 21-14. In order to limit the resources required to generate and receive CCMs, the following restrictions apply to the format of the CCM:

a) The Maintenance Domain Name and Short MA Name are encoded in a manner such that an MP can treat all of the fields from the Maintenance Domain Name Format field through the Short MA Name field as a unit when deciding whether a received CCM does or does not belong to the receiving MP's MA. That is, the MP can perform a binary comparison of these fields in a received CCM to the fields it would transmit in its own CCMs. This means, for example, that two Maintenance Domain Names differing, e.g., only by trailing spaces or by upper/lower case substitutions, can be interpreted to denote different MAs.

b) The portion of the PDU allocated for the MAID is limited to 48 octets, in order to minimize the memory requirements of a hardware implementation of a MEP.

An MP shall be able to receive and process any valid CCM PDU that is 128 octets in length or less, starting with the MD Level/Version octet and including the End TLV. An MP shall not transmit a CCM PDU exceeding this length. An MP may discard as invalid any received CCM PDU that exceeds this length.

Table 21-14—CCM format

Field	Octet
Common CFM Header	1–4
Sequence Number	5–8
Maintenance association Endpoint Identifier	9–10
Maintenance Association Identifier	11–58
Defined by ITU-T G.8013/Y.1731	59–74
Reserved for definition in future versions of the protocol [a]	
Optional CCM TLVs	First TLV Offset + 5 [b]
End TLV (0)	First TLV Offset + 5, if no Optional CCM TLVs are present

[a] This field has 0 length in this version 0 of CFM. It is shown in order to stress that additional information can be present in future versions of CFM, and that a version 0 receiver ignores its contents, if present.
[b] Octet 75 for transmitted CCMs.

21.6.1 Flags

(1 octet) The Flags field of the Common CFM Header is split into four parts for the CCM as follows:

a) RDI field (21.6.1.1)
b) Reserved field (21.6.1.2)
c) CCM Interval field (21.6.1.3)
d) Traffic field (21.6.1.4)

21.6.1.1 RDI

The MSB of the Flags field is the RDI bit. This bit is set to 1 if the transmitting MEP's presentRDI variable (20.9.6) is set, and 0 if not.

21.6.1.2 Reserved

The bits of the Flags field not including the RDI field, the Traffic field, and the CCM Interval field are set to 0 by the transmitting MP, and are not to be examined by the receiving MP [item b) in 20.51.2].

21.6.1.3 CCM Interval

The least significant 3 bits of the Flags field constitute the CCM Interval field. The CCM Interval field is encoded as specified in Table 21-15.

NOTE—The maximum CCM Lifetime in Table 21-15 is equal to 3.5 times the CCM Interval. The minimum CCM Lifetime is the maximum CCM Lifetime minus 1/4 of the CCM Interval, the minimum required granularity of the timer variables CCIwhile, rMEPwhile, errorCCMwhile, and xconCCMwhile.

Validation Test: The CCM Interval field does not contain the value 0.

21.6.1.4 Traffic field

In the case of a PBB-TE MA or Infrastructure Segment MA, the second most significant bit of the Flags field is the Traffic bit. This bit if supported, is used to indicate the presence of backbone service instances in the monitored TESI or the assignment of TESIs in the monitored Infrastructure Segments. This bit is set to 1

Table 21-15—CCM Interval field encoding

Transmission Interval	max. CCM Lifetime	min. CCM Lifetime	CCM Interval field
invalid			0
3 1/3 ms (300 Hz)	11 2/3 ms	10 5/6 ms	1
10 ms	35 ms	32.5 ms	2
100 ms	350 ms	325 ms	3
1 s	3.5 s	3.25 s	4
10 s	35 s	32.5 s	5
1 min	3.5 min	3.25 min	6
10 min	35 min	32.5 min	7

if the transmitting MEP's presentTraffic variable (20.9.8) is set in the case of a PBB-TE MEP or the transmitting MEP's ISpresentTraffic variable (20.9.10) is set in the case of a Infrastructure Segment MEP, and 0 if not. This field is not examined if the receiving MPs are not PBB-TE or Infrastructure Segment MEPs supporting the traffic field.

21.6.2 First TLV Offset

(1 octet) The First TLV Offset field of the Common CFM Header in a CCM is transmitted as 70.

Validation Test: The First TLV Offset field of the Common CFM Header in a CCM contains a value greater than or equal to 70.

21.6.3 Sequence Number

(4 octets) A MEP either transmits a 0 in this field or copies to it the contents of the CCIsentCCMs variable (20.10.2).

21.6.4 Maintenance association Endpoint Identifier

(2 octets) Contains an integer value. This TLV specifies from which MEP the CCM was transmitted.

Validation Test: MEPID is in the range 1–8191.

21.6.5 Maintenance Association Identifier

(48 octets) This field contains the MAID of the transmitting MEP. It is divided into six subfields, plus, if necessary, a pad of octets contains 0 to fill out its fixed length. The subfields are as follows:

a) Maintenance Domain Name Format (21.6.5.1)
b) Maintenance Domain Name Length (21.6.5.2)
c) Maintenance Domain Name (21.6.5.3)
d) Short MA Name Format (21.6.5.4)
e) Short MA Name Length (21.6.5.5)
f) Short MA Name (21.6.5.5)

The total length of these fields, including padding, if present, shall be exactly 48 octets. There are two possible formats of the Maintenance Association Identifier field, as shown in Table 21-16 and Table 21-17, depending on whether the Maintenance Domain Name is present.

Table 21-16—CCM Maintenance Association Identifier field format: Maintenance Domain present

Field	Octet
Maintenance Domain Name Format (not 1)	1
Maintenance Domain Name Length	2
Maintenance Domain Name	3 – (mdnl [a] + 2)
Short MA Name Format	(mdnl + 3)
Short MA Name Length	(mdnl + 4)
Short MA Name	(mdnl + 5) – (mdnl + smanl [b] + 4)
0 pad, if necessary	(mdnl + smanl + 5) – 48

[a] Maintenance Domain Name Length.
[b] Short MA Name Length.

Table 21-17—CCM Maintenance Association Identifier field format: Maintenance Domain not present

Field	Octet
Maintenance Domain Name Format (1)	1
Short MA Name Format	2
Short MA Name Length	3
Short MA Name	4 – (smanl [a] + 3)
0 pad, if necessary	(smanl + 4) – 48

[a] Short MA Name Length.

21.6.5.1 Maintenance Domain Name Format

(1 octet) Specifies the format of the Maintenance Domain Name field. The Maintenance Domain Name Format is encoded according to Table 21-18.

21.6.5.2 Maintenance Domain Name Length

(1 octet) Specifies the length in octets of the Maintenance Domain Name field. Not present if the Maintenance Domain Name Format field specifies “No Maintenance Domain Name present” (1).

Validation Test: The Maintenance Domain Name Length in a CCM, if present, is greater than or equal to 1, and less than or equal to 43.

Table 21-18—Maintenance Domain Name Format

Maintenance Domain Name Format field	Value
Reserved for IEEE Std 802.1	0
No Maintenance Domain Name present	1
Domain Name-based string [a]	2
MAC address + 2-octet integer	3
Character string [b]	4
Reserved for IEEE Std 802.1	5–31
Defined by ITU-T G.8013/Y.1731	32–63
Reserved for IEEE Std 802.1	64–255

[a] This is a string the terminal substring of which is an IETF RFC 1035 DNS Name, and the remainder of which is a text string, following the syntax of a DNS Name, denoting the identity of a particular Maintenance Domain.
[b] This is an IETF RFC 2579 DisplayString, with the exception that character codes 0–31 (decimal) are not used.

21.6.5.3 Maintenance Domain Name

(Length specified by the Maintenance Domain Name Length field) Contains the Maintenance Domain Name, in the format specified by the Maintenance Domain Name Format field. Not present if the Maintenance Domain Name Format field specifies “No Maintenance Domain Name present” (1).

21.6.5.4 Short MA Name Format

(1 octet) Specifies the format of the Short MA Name field. The Short MA Name Format is encoded according to Table 21-19.

Table 21-19—Short MA Name Format

Short MA Name Format field	Value
Reserved for IEEE Std 802.1	0
Primary VID	1
Character string [a]	2
2-octet integer	3
IETF RFC 2685 VPN ID	4
Reserved for IEEE Std 802.1	5–31
ICC-based format as specified in ITU-T G.8013/Y.1731	32
Defined by ITU-T G.8013/Y.1731	33–63
Reserved for IEEE Std 802.1	64–255

[a] This is an IETF RFC 2579 DisplayString, with the exception that character codes 0–31 (decimal) are not used.

21.6.5.5 Short MA Name Length

(1 octet) Specifies the length in octets of the Short MA Name field.

Validation Test: The Short MA Name Length in a CCM contains a value greater than or equal to 1.

Validation Test: The Short MA Name Length in a CCM does not indicate that the Short MA Name runs over the 48-octet limit for the MAID.

21.6.5.6 Short MA Name

(Length specified by the Short MA Name Length field) Contains the Short MA Name, in the format specified by the Short MA Name Format field.

21.6.6 Defined by ITU-T G.8013/Y.1731

(16 octets) The use of this field is defined by ITU-T G.8013/Y.1731. A value of 0 should be transmitted in this field.

21.6.7 Optional CCM TLVs

The following TLVs should be included, as allowed by their specifications, in every CCM transmitted:

a) Sender ID TLV (21.5.3)
b) Port Status TLV (21.5.4)
c) Interface Status TLV (21.5.5)

The following TLV may be included in any CCM transmitted:

d) Organization-Specific TLV (21.5.2)

The Optional CCM TLVs in this subclause may be placed in any order by the MEP transmitting the CCM. The receiving MP shall not depend upon any particular ordering of the Optional CCM TLVs in a CCM for its proper operation.

21.7 LBM and LBR formats

The format of the LBM and LBR is shown in Table 21-20.

Table 21-20—LBM and LBR formats

Field	Octet
Common CFM Header	1–4
Loopback Transaction Identifier	5–8
Reserved for definition in future versions of the protocol [a]	
Additional LBM/LBR TLVs	First TLV Offset + 5 [b]
End TLV (0)	First TLV Offset + 5, if no Additional LBM/LBR TLVs are present

[a] This field has 0 length in this version 0 of CFM. It is shown in order to stress that additional information can be present in future versions of CFM, and that a version 0 receiver ignores its contents, if present.

[b] Octet 9 for transmitted LBMs.

21.7.1 Flags

(1 octet) In an LBM, the Flags field of the Common CFM Header is set to 0 by the transmitting MP, and is not examined by the receiving MP.

21.7.2 First TLV Offset

(1 octet) The First TLV Offset field of the Common CFM Header in an LBM or LBR is transmitted as 4.

Validation Test: The First TLV Offset field of the Common CFM Header in an LBM or LBR contains a value greater than or equal to 4.

21.7.3 Loopback Transaction Identifier

(4 octets) A MEP copies the contents of the nextLBMtransID variable (20.30.2) to this field.

21.7.4 Additional LBM/LBR TLVs

The following TLV shall be included in every LBM transmitted by a MEP to a MIP configured on a PBB-TE MA as specified in 21.7.5. The TLV will not be present in any other type of MA.

a) PBB-TE MIP TLV (21.7.5)

The following TLV should be included in every LBM transmitted:

b) Sender ID TLV (21.5.3)

The following TLV can be included by management action in any LBM transmitted:

c) Data TLV (21.5.6)

The following TLV may be included in any LBM transmitted:

d) Organization-Specific TLV (21.5.2)

The PBB-TE MIP TLV, if present, shall be placed first. The other Additional LBM/LBR TLVs may be placed in any order by the MEP transmitting the LBM.

21.7.5 PBB-TE MIP TLV

Type = 9. Used only in MAs monitoring PBB-TE services. It enables MIPs to selectively intercept LBMs that are targeting them. The PBB-TE MIP TLV is not used if the target address of the LBM or LTM is associated with any of the values in the ESP-DA field of the monitored MA's ESPs; otherwise, it shall be present; The format of the PBB-TE MIP TLV is illustrated in Table 21-21.

Table 21-21—PBB-TE MIP TLV format

Field	Octet
Type = 9	1
Length	2–3
MIP MAC address	4–9
Reverse VID	10–11
Reverse MAC	12–17

Validation Test: The MIP MAC address field contains an individual MAC address.

Validation Test: The Reverse MAC field contains an Individual, or a group MAC address as specified in 21.7.5.3.

Validation Test: The Length field either is 8, indicating that no Reverse MAC field is present, or is 14, and thus contains the Reverse MAC field.

21.7.5.1 MIP MAC address

The MIP MAC address contains the destination MAC address for LBMs transmitted by the MEP [item b) in 12.14.7.3.2]. In the case of LTMs, this field in null.

21.7.5.2 Reverse VID

The Reverse VID field is used by the MIPs in order to set the vlan_identifier parameters on LBRs and LTRs. Its value is provided by the operator on the initiation of the LBM [item f) in 12.14.7.3.2] or the LTM [item e) in 12.14.7.4.2]. In the case of point-to-point TESIs, its value is the ESP-VID of the MA's ESP that has the MEP's MAC address in its ESP-DA field.

21.7.5.3 Reverse MAC

This Reverse MAC field refers to the ESP-SA of any of the point-to-point ESPs of the MA, if the LBM/LTM is initiated on a root PBB-TE MEP or to the ESP-DA of the point-to-multipoint ESP of the MA, if the LBM/LTM is initiated on any of the leaf MEPs.

21.8 LTM format

The format of the LTM is shown in Table 21-22.

Table 21-22—LTM format

Field	Octet
Common CFM Header	1–4
LTM Transaction Identifier	5–8
LTM TTL	9
Original MAC Address	10–15
Target MAC Address	16–21
Reserved for definition in future versions of the protocol [a]	
Additional LTM TLVs	First TLV Offset + 5 [b]
End TLV (0)	First TLV Offset + 5, if no Additional LTM TLVs are present

[a] This field has 0 length in this version 0 of CFM. It is shown in order to stress that additional information can be present in future versions of CFM and that a version 0 receiver ignores its contents, if present.
[b] Octet 22 for transmitted LTMs.

21.8.1 Flags

(1 octet) In the LTM, the Flags field of the Common CFM Header specifies certain options as shown in Table 21-23.

Table 21-23—LTM Flags field

Mnemonic	Meaning	Bit
UseFDBonly	If set, indicates that only MAC addresses learned in a Bridge's FDB, and not information saved in the MIP CCM Database, is to be used to determine the Egress Port.	8 (MSB)
Reserved	Transmitted as 0, and ignored by the receiver.	7–1

21.8.2 First TLV Offset

(1 octet) The First TLV Offset field of the Common CFM Header in an LTM is be transmitted as 17.

Validation Test: The First TLV Offset field of the Common CFM Header in an LTM contains a value greater than or equal to 17.

21.8.3 LTM Transaction Identifier

(4 octets) A MEP copies the contents of the nextLTMtransID variable (20.41.1) to this field.

21.8.4 LTM TTL

(1 octet) The number of hops remaining to this LTM. Decremented by 1 by each Linktrace Responder that handles the LTM. One less than this value is returned in the LTR. If 0 or 1 on input, the LTM is not transmitted to the next hop. If 0 on input, no LTR is returned. The value of the LTM TTL field in the LTM transmitted by the originating MEP is controlled by a managed object [item d) in 12.14.7.4.2]; the default value if none is specified is 64.

21.8.5 Original MAC Address

(6 octets) The MAC address of the MEP that originated the LTM. This can be different from the source MAC address of an LTM because each MIP along the path puts its own MAC address in the source MAC address field, while retaining the Original MAC Address Field.

Validation Test: The Original MAC Address field contains an Individual, and not a Group, MAC address.

21.8.6 Target MAC Address

(6 octets) Specifies an individual MAC address, the path to which the LTM is intended to trace. Any individual MAC address can be specified in this field. See also 20.3.1.

Validation Test: The Target MAC Address field contains an Individual, and not a Group, MAC address.

21.8.7 Additional LTM TLVs

The following TLV shall be included in every LTM by each MP originating or forwarding an LTM:

a) LTM Egress Identifier TLV (21.8.8)

The following TLVs may be included in an LTM by each MP originating or forwarding an LTM:

b) Sender ID TLV (21.5.3)
c) Organization-Specific TLV(s) (21.5.2)

The following TLV shall be included in every LTM transmitted by a MEP configured on a PBB-TE MA. The TLV will not be present in any other type of MA.

d) PBB-TE MIP TLV (21.7.5)

The Additional LTM TLVs may be placed in any order by the MP transmitting the LTM.

21.8.8 LTM Egress Identifier TLV

Type = 7. Identifies the MEP Linktrace Initiator that is originating, or the Linktrace Responder that is forwarding, this LTM. The low-order (highest numbered) six octets contain an EUI-48 IEEE MAC address unique to the system in which the MEP Linktrace Initiator or Linktrace Responder resides. The high-order (lowest numbered) two octets contain an integer value sufficient to uniquely identify the transmitted LTM; a constant value (e.g., 0) is sufficient for this purpose, since a Bridge initiates or forwards only a single copy of an LTM. The format of the LTM Egress Identifier TLV is illustrated in Table 21-24.

Table 21-24—LTM Egress Identifier TLV format

Field	Octet
Type = 7	1
Length	2–3
Egress Identifier	4–11

NOTE—For most Bridges, the address of any MAC attached to the Bridge will suffice for the low-order six octets, and 0 for the high-order octets. In some situations, e.g., if multiple virtual Bridges utilizing emulated LANs are implemented in a single physical system, the high-order two octets can be used to differentiate among the transmitting entities.

21.9 LTR format

The format of the LTR is shown in Table 21-25.

Validation Test: The Reply Ingress TLV (21.9.8), the Reply Egress TLV (21.9.9), or both, are present.

21.9.1 Flags

(1 octet) In the LTR, the Flags field of the Common CFM Header specifies certain options as shown in Table 21-26.

Table 21-25—LTR format

Field	Octet
Common CFM Header	1–4
LTR Transaction Identifier	5–8
Reply TTL	9
Relay Action	10
Reserved for definition in future versions of the protocol [a]	
Additional LTR TLVs	First TLV Offset + 5 [b]
End TLV (0)	First TLV Offset + 5, if no Additional LTR TLVs are present

[a] This field has 0 length in this version 0 of CFM. It is shown in order to stress that additional information can be present in future versions of CFM, and that a version 0 receiver ignores its contents, if present.

[b] Octet 11 for transmitted LTRs.

Table 21-26—LTR Flags field

Mnemonic	Meaning	Bit
UseFDBonly	Copied from LTM.	8 (MSB)
FwdYes	The LTM was (1) or was not (0) forwarded.	7
TerminalMEP	The MP reported in the Reply Egress TLV (Reply Ingress TLV, if the Reply Egress TLV is not present) is a MEP.	6
Reserved	Copied from LTM.	5–1

21.9.2 First TLV Offset

(1 octet) The First TLV Offset field of the Common CFM Header in an LTR is transmitted as 6.

Validation Test: The First TLV Offset field of the Common CFM Header in an LTR contains a value greater than or equal to 6.

21.9.3 LTR Transaction Identifier

(4 octets) The value from the LTM Transaction Identifier field in the LTM that triggered the transmission of this LTR.

21.9.4 Reply TTL

(1 octet) One less than the value from the LTM TTL field in the LTM that triggered the transmission of this LTR. If the LTM TTL field contained a 0, no LTR is transmitted.

21.9.5 Relay Action

(1 octet) Reports how the data frame targeted by the LTM would be passed through the MAC Relay Entity to the Egress Bridge Port, as shown in Table 21-27.

Validation Test: The value in the Relay Action field is one of the values enumerated in 21.9.5.

Table 21-27—Relay Action field values

Mnemonic	Relay action	Value
RlyHit	The LTM reached an MP whose MAC address matches the target MAC address.	1
RlyFDB	The Egress Port was determined by consulting the FDB [item a) in 20.47.1.2].	2
RlyMPDB	The Egress Port was determined by consulting the MIP CCM Database [item b) in 20.47.1.2].	3

21.9.6 Additional LTR TLVs

The following TLV shall be included in an LTR according to 20.3.2:

a) LTR Egress Identifier TLV (21.9.7)

One or both of the following TLVs shall be included in an LTR according to 20.3.2:

b) Reply Ingress TLV (21.9.8)
c) Reply Egress TLV (21.9.9)

The following TLVs may be included in an LTR:

d) Sender ID TLV (21.5.3)
e) Organization-Specific TLV (21.5.2)

The Additional LTR TLVs may be placed in any order by the MP transmitting the LTR. The receiving MEP shall not depend upon any particular ordering of the Additional LTR TLVs in an LTR for its proper operation.

21.9.7 LTR Egress Identifier TLV

Type = 8. Identifies the source and destination of the LTM that triggered transmission of this LTR. The format of the LTR Egress Identifier TLV is illustrated in Table 21-28.

Table 21-28—LTR Egress Identifier TLV format

Field	Octet
Type = 8	1
Length	2–3
Last Egress Identifier	4–11
Next Egress Identifier	12–19

21.9.7.1 Last Egress Identifier

(8 octets) Identifies the MEP Linktrace Initiator that originated, or the Linktrace Responder that forwarded, the LTM to which this LTR is the response. This field takes the same value as the LTM Egress Identifier TLV of that LTM, or the value 0, if no LTM Egress Identifier TLV was present in that LTM.

21.9.7.2 Next Egress Identifier

(8 octets) Identifies the Linktrace Responder that transmitted this LTR, and can forward the LTM to the next hop. This field takes the same value as the LTM Egress Identifier TLV of the forwarded LTM, if any. If the FwdYes bit of the Flags field is false, the contents of this field are undefined, i.e., any value can be transmitted, and the field is ignored by the receiver.

21.9.8 Reply Ingress TLV

Type = 5. The format of the Reply Ingress TLV is shown in Table 21-29. The Reply Ingress TLV is transmitted if and only if the Bridge Port on which the LTM was received has an MP in the MA specified by the LTM.

Table 21-29—Reply Ingress TLV format

Field	Octet
Type = 5	1
Length	2–3
Ingress Action	4
Ingress MAC Address	5–10
Ingress Port ID Length	11
Ingress Port ID Subtype	12
Ingress Port ID	13 – (Length + 3)

Validation Test: The value in the Ingress Action field is one of the values enumerated in 21.9.8.1.

Validation Test: The Ingress MAC Address field contains an Individual, and not a Group, MAC address.

Validation Test: The Length field either is 7, indicating that no Ingress Port ID field is present, or is (9 + the Ingress Port ID Length field) or larger, and thus contains the Ingress Port ID field.

21.9.8.1 Ingress Action

(1 octet) Reports how the data frame targeted by the LTM would be received on the receiving MP, as shown in Table 21-30.

21.9.8.2 Ingress MAC Address

(6 octets) The MAC address that can be used as the Destination MAC address of an LBM intended for the ingress MP.

Table 21-30—Ingress Action field values

Mnemonic	Ingress action	Value
IngOK	The target data frame would be passed through to the MAC Relay Entity.	1
IngDown	The Bridge Port's MAC_Operational parameter is false. [a]	2
IngBlocked	The target data frame would not be forwarded if received on this Port due to active topology enforcement (8.6.1). (See Figure 22-1 to see how this is possible.)	3
IngVID	The ingress port is not in the member set of the LTM's VID, and ingress filtering is enabled, so the target data frame would be filtered by ingress filtering (8.6.2).	4

[a] This value could be returned, for example, by an operational Down MEP that has another Down MEP at a higher MD Level on the same Bridge Port that is causing the Bridge Port's MAC_Operational parameter to be false.

21.9.8.3 Ingress Port ID Length

(1 octet) The length, in octets, of the Ingress Port ID field. Cannot be 0. If the Length field of the Reply Ingress TLV is less than 8, then the Ingress Port ID Length field, Ingress Port ID Subtype field, and Ingress Port ID field are not present.

21.9.8.4 Ingress Port ID Subtype

(1 octet) The **port ID subtype**, as specified by IEEE Std 802.1AB, identifying the format of the Ingress Port ID field. If the Length field of the Reply Ingress TLV is less than 8, then the Ingress Port ID Subtype field is not present.

21.9.8.5 Ingress Port ID

(Length specified by the Ingress Port ID Length field) The Ingress Port, identified by the **port ID** specified by IEEE Std 802.1AB, in the chassis identified in the Sender ID TLV. If the Length field of the Reply Ingress TLV is less than 8, then the Ingress Port ID field is not present.

21.9.9 Reply Egress TLV

Type = 6. The format of the Reply Egress TLV is shown in Table 21-31. The Reply Egress TLV is included in the LTR if and only if the Bridge Port on which the LTM would be relayed could be identified, and is an MP in the MA specified by the LTM.

Validation Test: The value in the Egress Action field is one of the values enumerated in 21.9.9.1.

Validation Test: The Egress MAC Address field contains an Individual, and not a Group, MAC address.

Validation Test: The Length field either is 7, indicating that no Egress Port ID field is present, or is (9 + the Egress Port ID Length field) or larger, and thus contains the Egress Port ID field.

21.9.9.1 Egress Action

(1 octet) Reports how the data frame targeted by the LTM would be passed through Egress Bridge Port, as shown in Table 21-32.

Table 21-31—Reply Egress TLV format

Field	Octet
Type = 6	1
Length	2–3
Egress Action	4
Egress MAC Address	5–10
Egress Port ID Length	11
Egress Port ID Subtype	12
Egress Port ID	13 – (Length + 3)

Table 21-32—Egress Action field values

Mnemonic	Egress action	Value
EgrOK	The targeted data frame would be forwarded.	1
EgrDown	The Egress Port can be identified, but that Bridge Port's MAC_Operational parameter is false.	2
EgrBlocked	The Egress Port can be identified, but the data frame would not pass through the Egress Port due to active topology management (8.6.1), i.e., the Bridge Port is not in the Forwarding state.	3
EgrVID	The Egress Port can be identified, but the Bridge Port is not in the LTM's VID's member set, so would be filtered by egress filtering (8.6.4).	4

21.9.9.2 Egress MAC Address

(6 octets) The MAC address that can be used as the Destination MAC address of an LBM intended for the egress MP.

21.9.9.3 Egress Port ID Length

(1 octet) The length, in octets, of the Egress Port ID field. Cannot be 0. If the Length field of the Reply Egress TLV is less than 8, then the Egress Port ID Length field, Egress Port ID Subtype field, and Egress Port ID field are not present.

21.9.9.4 Egress Port ID Subtype

(1 octet) The **port ID subtype**, as specified by IEEE Std 802.1AB, identifying the format of the Egress Port ID field. If the Length field of the Reply Egress TLV is less than 8, then the Egress Port ID Subtype field is not present.

21.9.9.5 Egress Port ID

(Length specified by the Egress Port ID Length field) The Egress Port, identified by the **port ID** specified by IEEE Std 802.1AB, in the chassis identified in the Sender ID TLV. If the Length field of the Reply Egress TLV is less than 8, then the Egress Port ID field is not present.

22. CFM in systems

The relationships among MPs, and between the MPs and the other entities in a Bridge, are configurable. This configuration determines how CFM is used in a network and determines what parts of the Bridges and LANs comprising a network are protected by an MA. This clause provides both specifications and explanatory text to assist the implementor and system administrator to make efficient use of CFM. This clause:

a) Specifies how the EISS Multiplex Entity (6.17) is used to support MPs for multiple MAs associated with service instances supported by EISS-SAPs (22.1).
b) Specifies the creation of MPs in a Bridge (22.2).
c) Suggests methods for the efficient assignment of MD Levels to Maintenance Domains (22.3).
d) Specifies the use of MPs in stations (22.4).
e) Clarifies issues related to the scaling of resources required to run CFM (22.5).
f) Shows how MPs can be placed in Provider Bridges (22.6).
g) Suggests methods for using CFM in the enterprise environment, as opposed to the provider environment (22.7).
h) Provides guidance for the implementation of CFM in Bridges designed before the development of this standard (22.8).

NOTE—Clause 18 introduces the principles of CFM operation and the network architectural concepts that support it. Clause 19 breaks down the CFM protocol entities into their components. Clause 20 specifies the protocols operated by the components of each MP, and Clause 21 specifies the PDU formats used by those protocols.

22.1 CFM shims in Bridges

CFM is instantiated by configuring an MA, which maintains a single service instance. If multiple MAs, monitoring VLAN service instances, are configured on a single Bridge Port, the vlan_identifier parameter of the EISS and the MD Level in the CFM PDUs are used to multiplex CFM PDUs for the various MAs. Non-CFM data frames for these service instances are distinguished only by vlan_identifier: the particular service instance to which a non-CFM data frame belongs, if multiple service instances share the same VID, distinguished only by MD Level, is undetermined. MAs that monitor backbone or TESIs use I-SIDs or a combination of destination addresses, source addressees, and ESP-VIDs, respectively as service distinguishing parameters, instead of VIDs.

22.1.1 Preliminary positioning of MPs

Figure 22-1 illustrates how MPs are associated with particular VIDs or TESIs. The EISS Multiplex Entity (6.17) distributes frames across an array of ISS- or EISS-SAPs, each of which can have a “column” of MPs at different MD Levels and orientations (Up or Down). Several MEPs and MHFs are shown, distinguished by VID and MD Level in this manner.

NOTE—For MPs monitoring backbone service instances, it is the Backbone Service Instance Multiplex Entity (6.18) that is used to distinguish MPs by I-SIDs and associate MPs with particular backbone service instances as illustrated in Figure 26-2.

An MP that has its Passive SAP closer to the MAC Relay Entity than its Active SAP is called a “Down MEP” or “Down MHF,” because it points down, away from the MAC Relay Entity, in Figure 22-1. An MP that has its Passive SAP further away from the MAC Relay Entity than its Active SAP is called an “Up MEP” or “Up MHF.” The Bridge Port in Figure 22-1 is configured with five Up MEPs, three Up MHFs, three Down MHFs, and three Down MEPs. A single LOM is positioned below the per-VID Down MEPs.

Figure 22-1 illustrates a Down MEP, at MD Level 1, configured on the ISS below the Bridge Port connectivity entity. The service instance its MA protects encompasses all data frames passing through the Bridge Port, no matter what VID they are associated with.

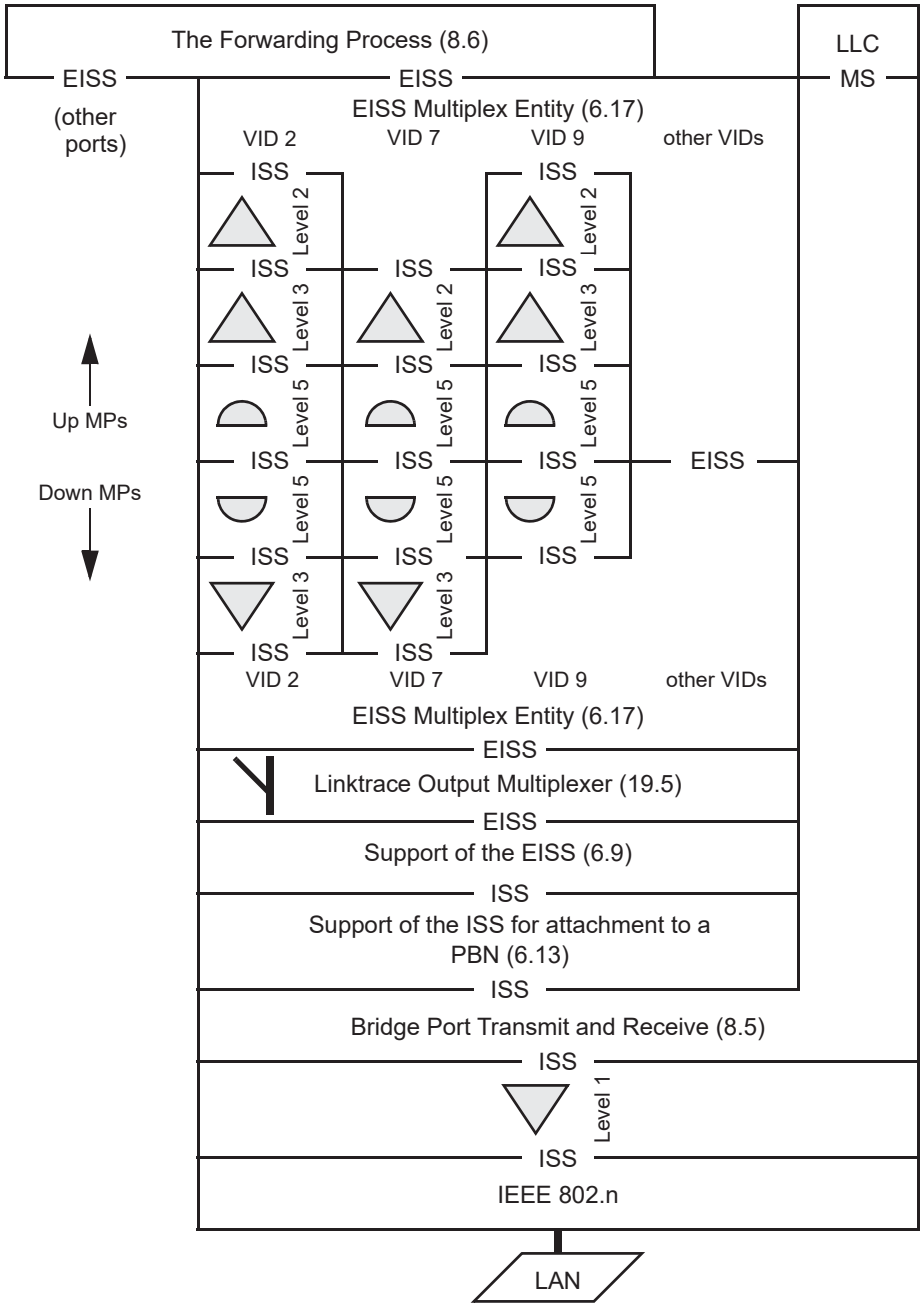

Figure 22-1—MEPs and MIPs distinguished by VID (incomplete picture)

22.1.2 CFM and the Forwarding Process

Figure 22-1 is incomplete, because it does not illustrate the relationship of CFM to the various components of the Forwarding Process (8.6). These components are illustrated in Figure 8-12. Readers can notice two facts about Figure 8-12:

a) The functions in Figure 8-12 can be divided into two groups. The first group, described in 8.6.1 through 8.6.5, consists of filtering functions that determine a set of potential transmission ports for

each frame received at a reception port. The second group, described in 8.6.6 through 8.6.8, consists of queuing functions that control the transmission of the frame at each port in the resulting set of potential transmission ports.

b) The parameters passed from component to component in Figure 8-12 are exactly those of the EISS; therefore, each of the components in Figure 8-12 could be described as a shim.

From these facts, readers can reconstruct Figure 8-12 in a manner that is functionally identical, but is better suited to illustrate the relationship between CFM and the Forwarding Process. This reconstruction is shown in Figure 22-2.

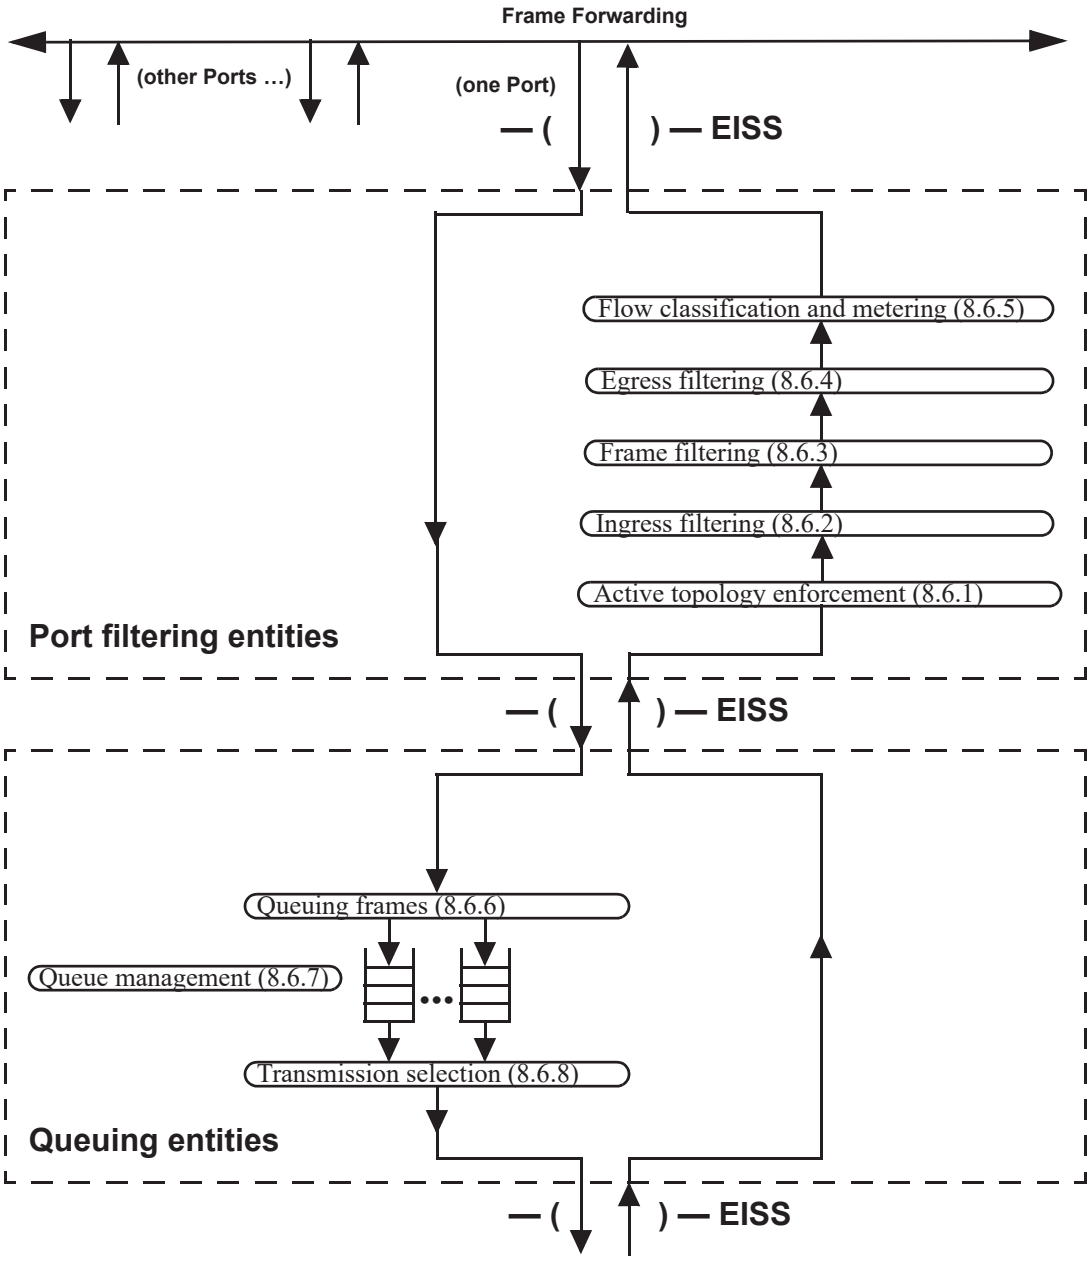

Figure 22-2—Alternate view of Forwarding process

22.1.3 Up/Down separation of MPs

An additional transformation to Figure 22-1 is required before the relationship between the Forwarding Process and CFM can be shown clearly. By adding a further pair of EISS Multiplex Entities between the Up MPs and the Down MPs in Figure 22-1, the entire set of Up MPs can be shown as a single shim, as can the entire set of Down MPs. This transformation is illustrated in Figure 22-3.

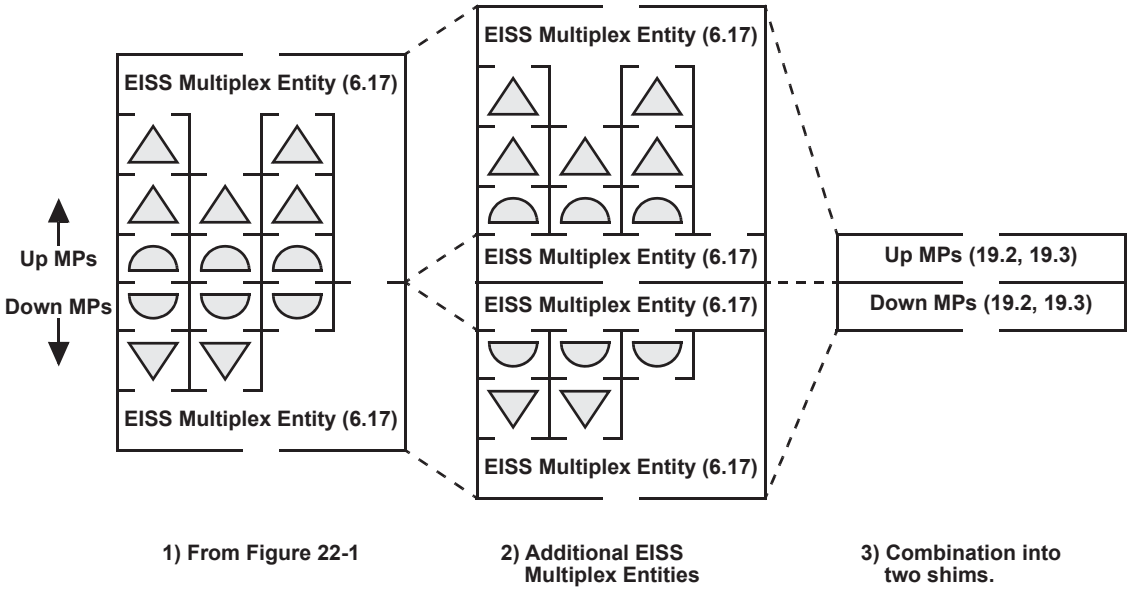

Figure 22-3—Combining per-VLAN MPs into two shims

Figure 22-4 combines Figure 22-1 with Figure 22-2, and shows the relationship of CFM to the various components of the Forwarding Process. MEPs and MHFs source and sink CFM PDUs. CFM PDUs are treated by the Port filtering entities in the same manner as ordinary data. Thus, the five Up MEPs of Figure 22-4 can transmit and receive CFM PDUs through the Bridge even when the Bridge Port is blocked. Similarly, the two Down MEPs in Figure 22-4 operate normally, transmitting CFM PDUs to and receiving them from the LAN, even if the Bridge Port is blocked. However, no frames, neither CFM PDUs nor ordinary data, can pass through the Port filtering entities when the VID to which those frames or CFM PDUs belong is filtered.

Also shown in Figure 22-4 are the positions of the DoSAPs and ISAPs introduced in Clause 18. The DoSAP provides access to a service instance (an instance of the MAC Service) and exists independently of any MA that might be created to protect it. The DoSAPs and ISAPs therefore can be associated with the specific inter-shim SAPs at the points indicated in Figure 22-4. The DoSAPs and ISAPs are attached to the Port filtering entities, because that is where the decisions are made on whether frames belonging to the service instance are or are not allowed to pass through the Bridge Port.[37] It does not matter to which side of the EISS Multiplex Entity one considers the DoSAPs and ISAPs to be attached. Except for the topmost Down MEP in each stack of Down MPs, the DoSAP is not coincident with the Passive SAP of the MEP protecting the DoSAP's service instance; the DoSAP is separated from its MA by the MHFs and/or MEPs at higher MD Levels. Even for that topmost Down MEP, an MHF for a higher MD Level can separate that MEP from its DoSAP. This gap is illustrated in Figure 22-5 and Figure 22-6, where the service instance, DoSAP to DoSAP, is shown in gray, but the MEPs protecting that service are separated from the DoSAPs by MHFs belonging to a service instance at a higher MD Level.

[37] The DoSAP is not attached to an MP's Passive SAP because the DoSAP and its associated service instance exist regardless of whether the service instance is protected by an MA.

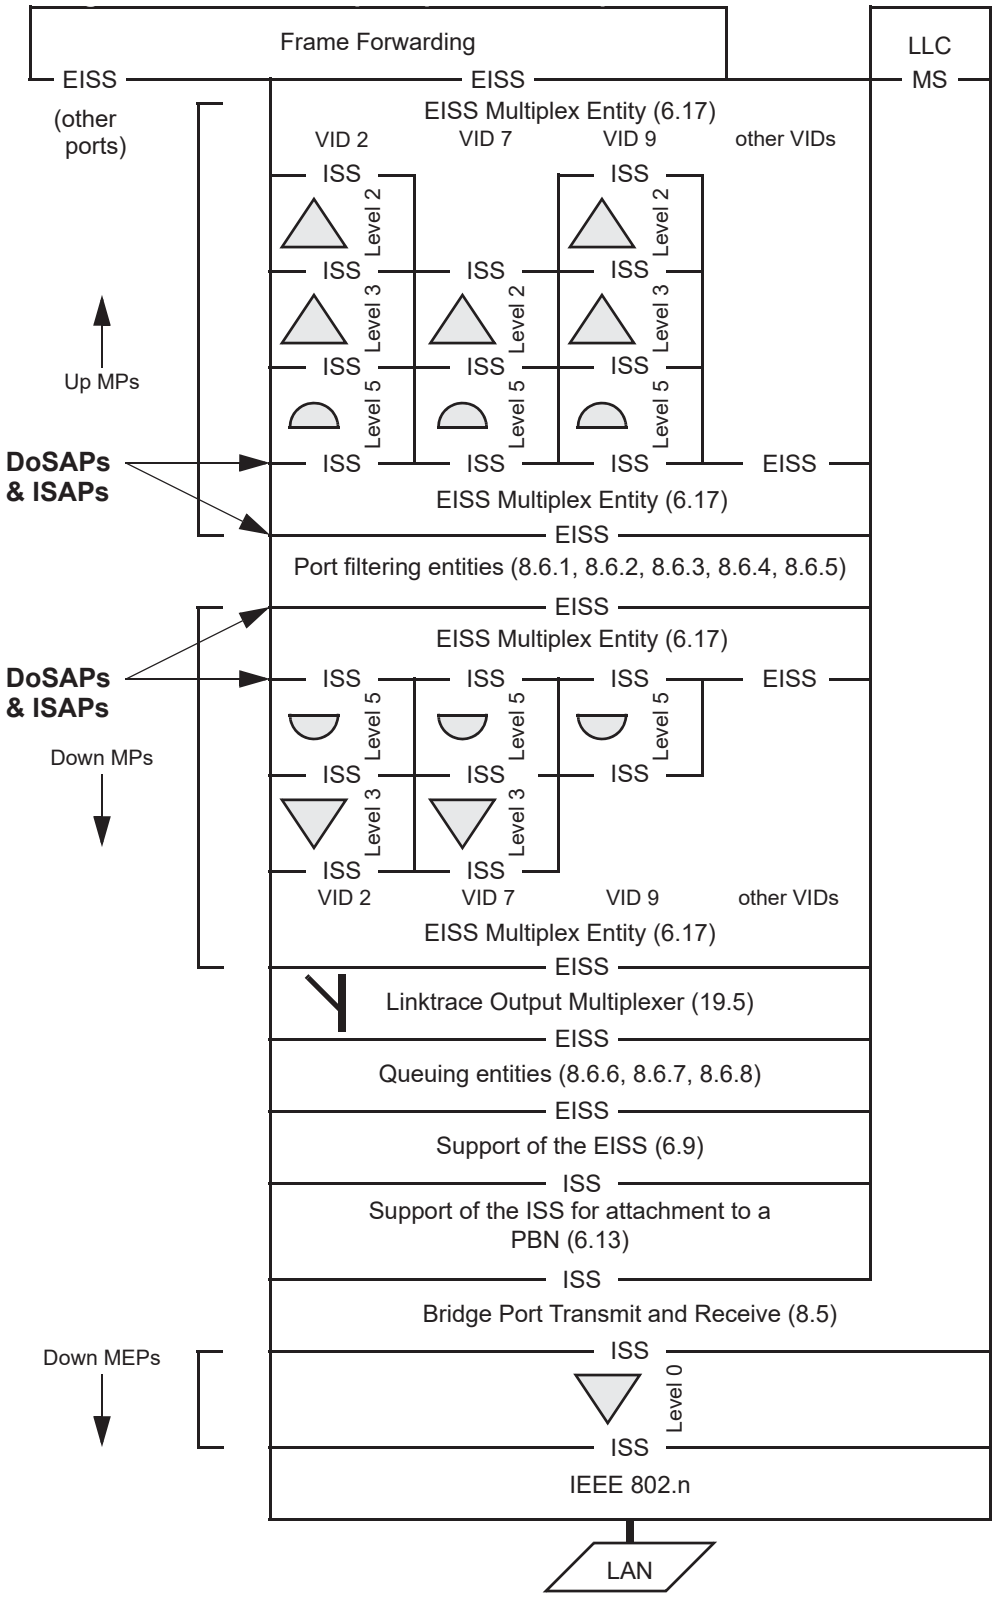

Figure 22-4—More complete picture of MP placement in a Bridge Port

In the “stack” of MPs on a single Bridge Port, the following rules apply:

a) All Up MEPs belonging to MAs that are attached to specific VIDs are placed above the Port filtering entities (8.6.1, 8.6.2, and 8.6.4). Separately for each VID, there can be from zero to eight Up MEPs, ordered by increasing MD Level, from the upper EISS toward Port filtering. In the case of PBB-TE MAs, more than one Up MEP can share the VID and MD Level.

b) For each MA there can be at most one MIP, consisting of an Up MHF just above, and a Down MHF just below, the Port filtering entities. Both MHFs are at the same MD Level, higher than the highest MEP on the same VID, if any. Backbone Service Instance MHFs use the Backbone Service Instance Multiplex Entity (6.18) and are placed as depicted in Figure 26-2.

c) Up to eight Down MEPs belonging to MAs that are attached to the same list of VIDs are placed between the Down MHF, if any, and the Queuing entities (8.6.6, 8.6.7, and 8.6.8). They are placed in order of decreasing MD Level, from the Port filtering entities to the Queuing entities, including any Down MHF.

d) No Down MEPs exist for PBB-TE MAs.

e) An LOM is positioned below the Down MPs belonging to MAs that are attached to specific VIDs to handle forwarded LTMs.

f) Up to eight Down MEPs, ordered from highest MD Level to lowest, belonging to MAs not attached to any specific VID, can be placed below Bridge Port connectivity (8.5.1). They are ordered by decreasing MD Level going away from the MAC Relay Entity (see also 22.1.8).

g) Up to 8 Up MEPs, ordered from highest MD Level to lowest, belonging to Backbone Service Instance MAs that are identified by the same I-SID, can be placed below the Bridge Port connectivity (8.5.1) using the Backbone Service Instance Multiplex Entity (6.18) as depicted in Figure 26-2. They are ordered by decreasing MD Level going away from the multiplexed SAP.

h) Up to 8 Down MEPs, ordered from highest MD Level to lowest, belonging to Backbone Service Instance MAs that are identified by the same I-SID, can be placed below the Bridge Port connectivity (8.5.1) using the Backbone Service Instance Multiplex Entity (6.18) as depicted in Figure 26-2. They are ordered by decreasing MD Level going away from the MAC Relay Entity.

i) All of the Down MEPs below Bridge Port connectivity have lower MD Levels than any Down MP attached to a VID that is emitted untagged by the Support of the EISS.

j) Any shim that introduces an EtherType tag insulates the MPs above and below it, removing any MD Level restriction between the separated groups of MPs.

A single Port on a Bridge could, in theory, have MHFs for multiple service instances at different MD Levels. However, that would require a vector of 4094 MD Level registers instead of one register to identify the CFM PDUs to be deflected to the Bridge’s Higher Layer Entities. This capability is optional.

22.1.4 Service instances over multiple Bridges

Figure 22-4 completes the sequence of expansions starting with Figure 18-5 and continuing with Figure 18-6 and Figure 18-7. In this sequence, Figure 22-4 illustrates Bridge Port b of Bridge 2 in Figure 18-5 through Figure 18-7. The service instances illustrated in those three figures all use VID 9 in Figure 22-4. The Up MEPs for VID 9 at MD Levels 3 and 2 are the Up MEPs protecting the provider MD Level and the operator MD Level service instances, respectively, and the pair of MHFs at MD Level 5 on VID 9 provide a customer MD Level MIP. Figure 22-4 also illustrates two other sets of service instances sharing the same Bridge Port using VIDs 2 and 7.

Additional views of service instances spanning two Bridges are shown in Figure 22-5 and Figure 22-6. Figure 22-5 shows a service instance protected by Up MPs, and Figure 22-6 shows a service instance protected by Down MPs.

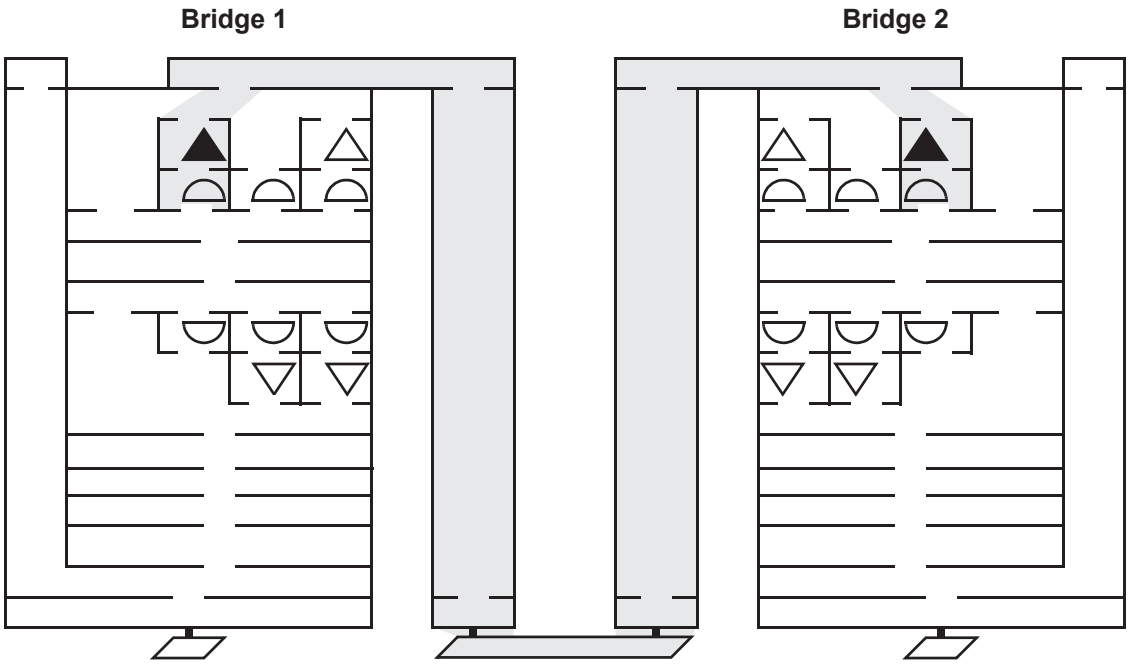

Figure 22-5—Service instance spanning two Bridges protected by Up MPs

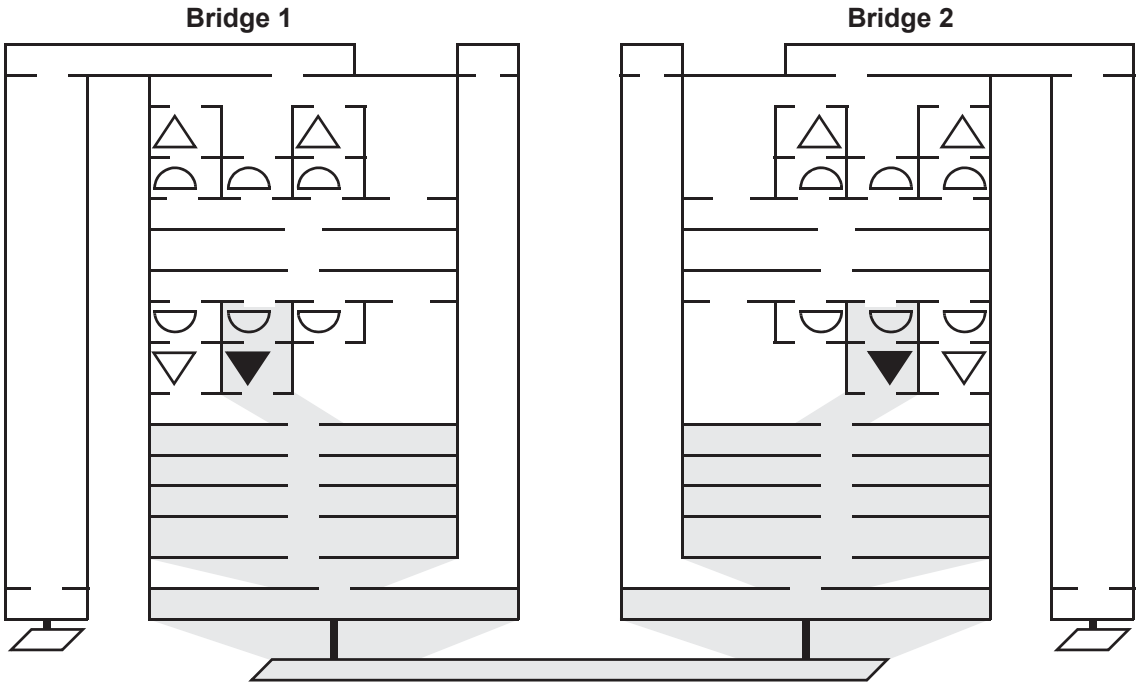

Figure 22-6—Service instance spanning two Bridges protected by Down MPs

22.1.5 Multiple VID service instances

A service instance can be implemented using multiple VIDs. It is always the case that the VLAN tag uniquely determines the VLAN service instance for a given frame. A VID-based MA or a PBB-TE MA with multiple VIDs does not require any more MIPs or MEPs than the corresponding MA with a single VID. All of the VIDs belonging to a given VID or TESI share the same MA. That is, one MAID is used for all CFM PDUs on the various VIDs in the same VID or TESI and Maintenance Domain. The choice of VID used to tag a given CFM PDU depends on the OpCode and the ESP, as specified in Clause 20.

22.1.6 Untagged CFM PDUs

A MEP placed anywhere below the Support of the EISS entity (6.9) or the Bridge Port connectivity entity (8.5.1) differs in three important respects from a MEP placed above the Support of the EISS entity:

a) The lower position would not have the Queuing entities available to it. For example, the reflection of a high-speed stream of LBMs (as LBRs) could seriously disrupt the flow of data frames, and thus bring into question the utility of the Queuing entities, CFM, or both.
b) A MEP in the lower position is necessarily VLAN untagged; the VLAN tagging functions are performed in the Support of the EISS entity.
c) A MEP in the lower position protects all data passing through the Bridge Port or if it is associated with a backbone service instance only data with this instance as specified in (26.8); it does not separately protect the different VLANs.

Point c) above does not mean that the lower position is the only one that can protect all of the traffic on a single link. MEPs placed above the Queuing entities can be associated with a VLAN whose VID is the PVID, for which this Bridge Port belongs to the untagged set. That VID can be statically configured in the member set to not be allowed to pass through the Frame filtering entity (8.6.3). MEPs so configured can then transmit and receive only untagged frames, and thus protect all of the data on the link. Their untagged CFM PDUs can be visible to complex “links” such as PBNs, even though the C-VLAN-tagged CFM PDUs are not visible inside the PBN.

The option to create MEPs below the Bridge Port connectivity entity for VID identified service instances cannot be omitted, however, because of considerations given in 22.1.8. This subclause also explains why only MEPs, and not MHFs, can be placed below the Bridge Port connectivity entity.

22.1.7 MPs and non-VLAN-aware Bridges

The positioning of MPs in Bridges that are not VLAN aware (i.e., MAC Bridges) is illustrated in Figure 22-7. Because there are no VLANs, no EISS Multiplex Entity is needed. However, the Up MPs are still above the Port filtering entities, so the transformation introduced in 22.1.2 is still retained.

Down MPs can be placed either above or below the Queuing entities and Bridge Port connectivity in Figure 22-7; the difference between the two locations is that:

a) In the upper location, frame queues are available to CFM, so that CFM frames and data frames can be scheduled appropriately for output, and
b) Placing a Down MEP in the lower location protects the LLC path used by the Higher Layer Entities, e.g., BPDUs, as well as the normal data forwarding path.

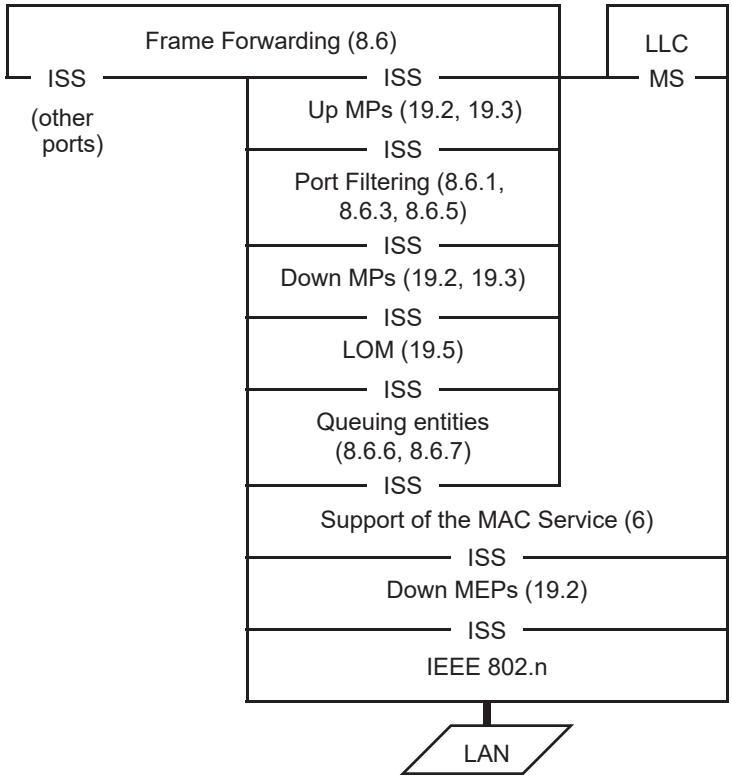

Figure 22-7—MP placement in a non-VLAN-aware Bridge Port

22.1.8 MPs and other standards

The relationship of MPs and the shims defined by two other standards, IEEE Std 802.1AX (Link Aggregation) and IEEE Std 802.1AE (MAC Security), is illustrated in Figure 22-8. This figure shows Down MEPs positioned both above and below Link Aggregation and illustrates a number of points.

MPs could, in theory, be placed either above or below the MAC Security shim. No loss of data integrity beyond the protected link would be incurred by placing CFM below MAC Security; the only attacks that could be generated would be variants of a denial of service attack. However, there are several reasons for restricting MPs to positions above the MAC Security shim:

a) The denial of service attacks available by the introduction of bogus CFM PDUs have more potential for disrupting management operations, in more complex ways, than do attacks based on other unprotected protocols, namely those defined by IEEE Std 802.3. For example, bogus cross connect CCMs could be introduced, leading to undesirable interactions between different providers' management systems.
b) MAC Security ensures that all data frames are legitimate, in the sense that they were last transmitted by a trusted device. Allowing the introduction of unprotected CFM PDUs violates the principle that data frames and CFM PDUs follow the same paths, distinguished only by the CFM protocol encapsulation.
c) Allowing the CFM and MAC Security shims to be interchanged by management operations could significantly complicate the implementation of a Bridge, with no commensurate benefit to the user.

As described in 22.1.6, placing an MP below the Queuing entities, whether above or below the Link Aggregation shim, is not desirable, as that MP is not able to use the Queuing entities. For this reason, it is preferable to use a Down MEP that is attached to a specific VID, and is thus above the Queuing entities, to protect the link.

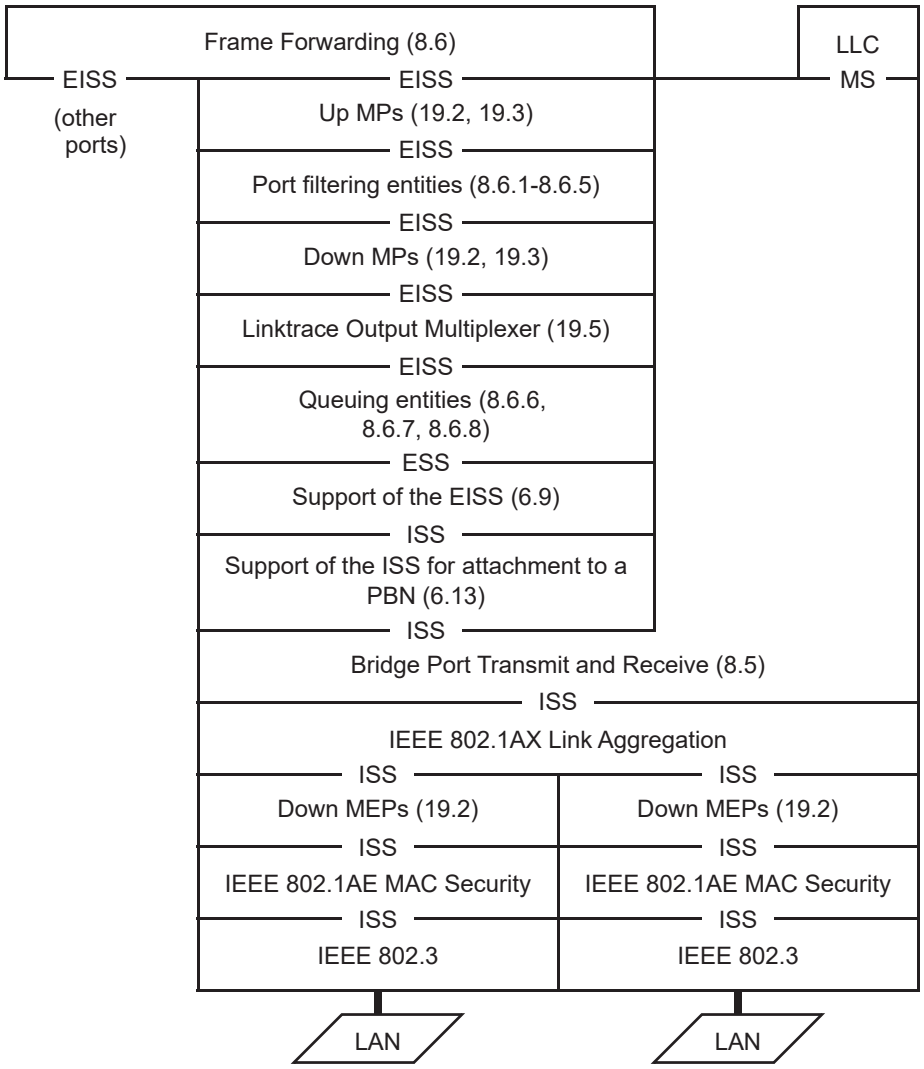

Figure 22-8—MP placement relative to other standards

When Link Aggregation is employed, Down MEPs attached to no VID can be useful for protecting the individual IEEE 802.3 LANs. The method used in Link Aggregation to select the outgoing IEEE 802.3 link is undefined. It is not necessarily possible for an MP above the Queuing entities to protect all of a Bridge Port's data; CCM PDUs could take one IEEE 802.3 link, and data frames another. Therefore, provision is made in this standard for configuring Down MEPs in an MA attached to no VID below the Bridge Port connectivity entity, and below Link Aggregation, when employed. The following considerations are important when configuring Down MEPs:

d) It is best to disable the Bridge Port before issuing a high-speed stream of LBRs (relative to the physical link speed), either from or toward a Down MEP attached to no VID; otherwise, the Queuing entities might be unable to achieve any guarantees for throughput or latency.

e) The rate of CCMs generated by Down MEPs attached to VIDs should be taken into account when configuring the Queuing entities to achieve particular guarantees for throughput or latency.

f) If Link Aggregation is present, Down MEPs attached to no VID should be configured below Link Aggregation.

g) The creation of MHFs below Link Aggregation presents two problems that preclude it from this standard:
   1) IEEE Std 802.3 provides no means for Link Aggregation to use a destination MAC address to direct a CFM PDU down the correct link to reach a particular MP at one or the other end of that link.
   2) The utility of isolating the short segment between the Port filtering entities and the links being aggregated, which is completely internal to a Bridge, is very limited, especially considering the wide range of methods employed for implementing Link Aggregation.

22.1.9 CFM and IEEE 802.3 OAM

The following differences between CFM and the IEEE Std 802.3 specification of Operations, Administration, and Maintenance (OAM) are relevant to making a decision whether to employ one, the other, or both of these protocols.

a) IEEE 802.3 OAM has provision for a loopback mode in which all frames are returned to the sender. CFM does not.

NOTE—IEEE 802.3 OAM confines loopbacked frames to the individual IEEE 802.3 LAN, effectively disabling any attached Bridge Port. Use of simple frame loopback through a Bridged Network could be expected to seriously impact the operation of the network.

b) IEEE 802.3 OAM has provision for acquiring statistics from a remote interface. CFM does not.
c) IEEE 802.3 OAM has provision for generating error conditions when configured thresholds are exceeded for parameters such as the number of frames received with Cyclic Redundancy Check (CRC) errors. CFM does not.
d) IEEE 802.3 OAM has provision for organizations other than IEEE 802 to define both new TLVs and new operation codes using OUIs/CIDs. CFM allows only TLVs to be defined using OUIs/CIDs.
e) IEEE 802.3 OAM performs a continuity check once per second. CFM can be programmed to perform the continuity check over a wide range of intervals.
f) IEEE 802.3 OAM is defined only for IEEE 802.3 media. CFM can be used over any medium, or bridged network, that can carry IEEE 802 frames.
g) IEEE 802.3 OAM protects a single link. CFM can protect a single link or a network of bridged networks, over multiple nested ranges.
h) CFM can protect the connectivity of shared media. IEEE 802.3 OAM has no such capability.
i) CFM can perform in-band loopback tests at any rate up to the physical line rate, during normal operations. IEEE 802.3 OAM has no such capability.
j) CFM can perform Linktrace functions through a Bridged Network. IEEE 802.3 OAM has no such capability.
k) CFM can detect unintentional connectivity, as well as lack of connectivity. IEEE 802.3 OAM cannot.

22.2 Maintenance Entity creation

MPs are created using the managed objects described in 12.14. Before a MEP or MHF can be created, either an entry in the Default MD Level managed object, or the Maintenance Domain and MA to which the MEP or MHF belongs, are created. In this context, a Default MD Level managed object, Maintenance Domain, or an MA are strictly managed objects in a single Bridge. In order to realize the network-wide definitions of Maintenance Domains and MAs given in 18.1 and 18.2, the Bridges in a Maintenance Domain are configured with identical information in these managed objects. During transitional periods when this information is changing, Fault Alarms will likely be generated.

NOTE—The correct operation of CFM does not depend on the configuration restrictions in this subclause. Rather, violating these restrictions is likely to generate Fault Alarms that might or might not be erroneous. In other words, if no Fault Alarms are generated, then all monitored MAs have connectivity. If any Fault Alarm is generated, then either

connectivity has been lost or the network is improperly configured. Determining which of these two is the cause of a Fault Alarm depends on the intentions of the operators and is therefore beyond the scope of this standard.

22.2.1 Creating Maintenance Domains and MAs

The operator creates either a Default MD Level managed object or a Maintenance Domain managed object in a Bridge for every Maintenance Domain whose CFM PDUs can pass through that Bridge and are to be processed. The operator can also create a MA managed object in a Bridge for some or all of the MAs whose CFM PDUs can pass through that Bridge and are to be processed. Whether a service instance can pass through a Bridge depends on the following:

a) Enable Ingress Filtering per-Bridge Port parameter (8.6.2).
b) Static Filtering Entries (8.8.1).
c) Static VLAN Registration Entries (8.8.2).
d) PIP configuration parameters (6.10).
e) CBP configuration parameters (6.11).
f) Dynamic VLAN Registration Entries (8.8.5).
g) Operation of MSTP (Clause 13), which in turn, can be affected by the state of the MAC_Operational parameters (IEEE Std 802.1AC) of the ISSs in the Bridge Port.

The first five of these methods are altered only by modifying managed objects and can therefore be considered static for the purposes of configuring CFM. The last two methods are dynamic, in that they depend not only on configuration, but on protocols that respond to network events, such as the addition or loss of a link or Bridge. For example, a VLAN can pass through a Bridge unless there is a Static VLAN Registration Entry prohibiting its VID from passing through every Bridge Port, and Ingress Filtering is enabled on every Bridge Port. If a Bridge's Maintenance Domain requires only insignificant resources to support MHF configuration, then the most reliable network is one that assumes that all service instances will require MHFs at some MD Level higher than that of that Maintenance Domain.

22.2.2 Creating MEPs

There are four kinds of Maintenance Association managed objects: those that are attached to one or more specific VIDs in the Bridge, those that are attached to no VID, those that are attached to an I-SID, and those that are attached to a TESI or ECMP path.

Once the appropriate Maintenance Domain and MA have been created, a MEP can be created, modified, or deleted using the MA managed object defined in 12.14.6. MEPs are always created explicitly. MEP creation is controlled by creating a Maintenance association Endpoint managed object using the following parameters:

a) Whether the MA to which the MEP belongs is associated with specific VID(s), I-SID, TESI, or ECMP path, and if so, which parameters [item b) in 12.14.6.1.3], including a specification of the MA's Primary VID [item d)in 12.14.7.1.3].
b) Whether the MEP is a Down MEP (pointing away from the MAC Relay Entity), or an Up MEP, (pointing toward the MAC Relay Entity) [item c) in 12.14.6.3.2].

Given those two values in the MEP managed object, Table 22-1 shows where, in Figure 22-9, the MEP is created. In Figure 22-9, which shows a PNP or a CNP, the VID selects which of the MEP positions is selected for Table 22-1 column 3 values 1 and 4. Only one row of MEPs is shown in positions 1, 4, and 5, even though up to eight rows can exist at each of these points. Because the MEPs are always placed in order by MD Level, with the highest MD Level nearest the MHFs, at the center of each stack, there is thus no ambiguity. The third column, starting from the left, in the EISS Multiplex Entity depicted in Figure 22-9

corresponds to an ESP-VID or SPBM VID. Only MIPs can be placed in this column for a PNP. MEPs can be created on a CBP and PIP as shown in Figure 26-2.

Table 22-1—MEP creation

MA has VID [item b) in 12.14.6.1.3]	MEP direction [item c) in 12.14.7.1.3]	Position of MEP in Figure 22-9
Yes	Up	1
	Down	4
No	Up	disallowed
	Down	5

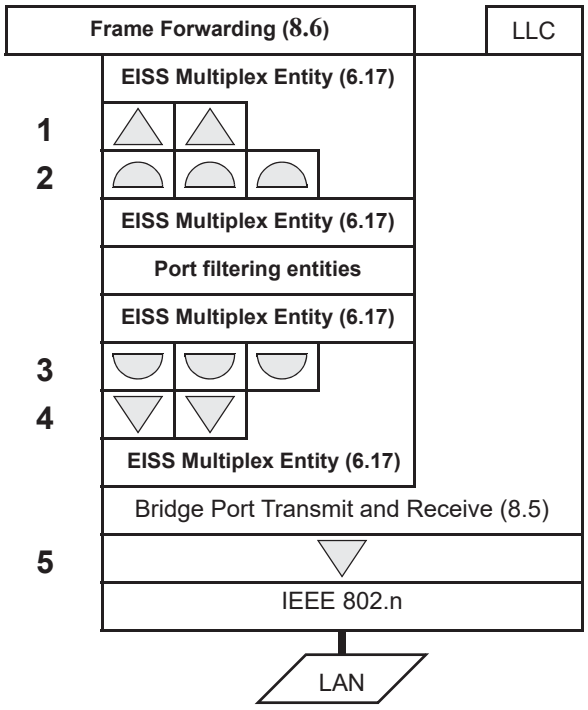

Figure 22-9—Creating MEPs and MIPs

If any MEPs are configured on an MA, then in any given Bridge, either all of those MEPs are Up MEPs or all of them are Down MEPs; a Bridge refuses to create an Up (Down) MEPs if a Down (Up) MEP already is configured in that MA in that Bridge. An MA can be configured with Up MEPs in one Bridge and Down MEPs in another Bridge or Station. Any given VID can be configured on any number of MAs (including zero) containing either Down MEPs or no MEPs at all, plus zero or one MA containing Up MEPs. No VID can be configured on more than one MA on which are configured Up MEPs.

These restrictions, along with the configuration errors in 22.2.4, enable MEPs to be configured so that they bound an MA, no matter what action is taken by the spanning tree protocols within a Maintenance Domain.

22.2.3 Creating MIPs

Managed objects control the creation of MIPs, but indirectly, rather than explicitly, as for MEPs. Every MA defined in a Bridge can cause the management entity to create MIPs on every Bridge Port. On each Bridge Port, the following conditions trigger the management entity to reevaluate the creation of MIPs for a given VID (or list of VIDs) or I-SID *x* on that port:

a) The Bridge is initialized.
b) A MEP is created or deleted on VID(s) or I-SID *x* on that Bridge Port.
c) An Up MEP is created or deleted on VID(s) *x*, which is (are) not allocated to a TESI, on any Bridge Port or an Up MEP is created or deleted on I-SID *x*.
d) A change occurs in whether VID(s) or I-SID *x* can or cannot pass through the Bridge Port (22.2.1).
e) A change occurs in the Default MD Level managed object (12.14.3).
f) A change occurs in a Maintenance Association managed object associated with VID(s) or I-SID *x*.

A MIP for VID-based service instances and TESIs is created by creating a pair of MHFs in positions 2 and 3 in Figure 22-9. MIPs associated with I-SIDs are created on the two sides of the multiplexed SAPs in the Backbone Service Instance Multiplex Entity as depicted in Figure 26-2. MAs that are associated with no VID are not considered in this subclause. For a given VID on a given Bridge Port, and in the absence of any of the configuration errors in 22.2.4, there are at most two MAs at each MD Level that can affect MIP creation, plus at most one entry in the Default MD Level managed object. If one or more of the configuration errors in 22.2.4 are present, this standard does not specify what MIPs the Bridge creates.

When required, the Maintenance Entity performs the MIP evaluation on each Bridge Port for each VID. For each Bridge Port *p* and service identifier *x*, which can be a list of VIDs, or an I-SID, the Maintenance Entity creates a list of active MD Levels. This list contains the following:

g) MD Level of each of the MAs (if any) that monitors service *x* and has a MEP configured on Bridge Port *p*.
h) MD Level of each of the MAs (if any) that monitors a service *x*, and has at least one Up MEP configured on some Bridge Port in this Bridge other than Bridge Port *p*.
i) MD Level of each of the MAs (if any) that monitors service *x* and has no MEPs configured on any Bridge Port in this Bridge.
j) MD Level of the entry in the Default MD Level managed object (12.14.3) for service *x*.

Exactly one MD Level *d* in this active list is eligible for MIP creation. It is the lowest MD Level in the list of active MD Levels such that there is no MEP configured on Bridge Port *p* and service *x* at MD Level *d* or at any higher MD Level. This is the lowest MD Level in the list, if there is no such MEP configured. The Maintenance Entity then uses Table 22-2 to determine whether the MIP is to be created.

Table 22-2—MIP creation

Enumeration [item d) in 12.14.3.1.3, item c) in 12.14.6.1.3, or item c) in 12.14.6.1.3]	A MEP is configured on Bridge Port *p*	MIP created
defMHFnone:	—	No
defMHFexplicit	False	No
	True	Yes
defMHFdefault	—	Yes

The enumeration controlling whether the MIP is created is taken from:

k) The Maintenance Association managed object [item c) in 12.14.6.1.3] for the MA that monitors service *x*, and has at least one Up MEP configured on some Bridge Port in the Bridge [see item h)]; or

l) That MA's Maintenance Domain managed object [item c) in 12.14.5.1.3], if that MA exists, but its Maintenance Association managed object contains the value defMHFdefer; or

m) The Default MD Level managed object [item d) in 12.14.3.1.3] if no such MA exists [see item j)].

The enumerated values used in the managed objects item d) in 12.14.3.1.3, item c) in 12.14.5.1.3, and item c) in 12.14.6.1.3 to control the creation of a MIP for a service instance identified by the parameter *x* on a Bridge Port are as follows:

n) **defMHFnone**—No MHFs can be created for this VID(s) or I-SID (the default value).

o) **defMHFdefault**—MHFs can be created for this VID(s) or I-SID on any Bridge Port through which the VID(s) or I-SID can pass where:

   1) There are no lower active MD levels, or

   2) There is a MEP at the next lower active MD level on the port.

p) **defMHFexplicit**—MHFs can be created for this VID(s) or I-SID only on Bridge Ports through which this VID(s) or I-SID can pass, and only if there is a MEP at the next lower active MD level on the port.

q) **defMHFdefer**—In the Maintenance Association managed object [item c) in 12.14.6.1.3] only, the control of MHF creation is deferred to the corresponding variable in the enclosing Maintenance Domain [item c) in 12.14.5.1.3].

22.2.4 CFM configuration errors

While making the MIP creation evaluation described in 22.2.3, or whenever a MEP is created or deleted, the management entity can encounter errors in the configuration. Because of this, the Management entity maintains a Configuration Error List managed object (12.14.4) that lists, for every VID or I-SID, the Bridge Ports that have MIP configuration errors. Every time the MIP creation evaluation is performed or a MEP is created or deleted, this list is updated to reflect which Bridge Ports and VIDs are in error and which are not. A Bridge Port is placed in the list if and only if one of the following errors occurs:

a) **CFMleak**—MA *x* is associated with a specific VID list or I-SID, one or more of the VIDs or I-SID in MA *x* can pass through the Bridge Port, no Up MEP is configured for MA *x* on the Bridge Port, no Down MEP is configured on any Bridge Port for MA *x*, and some other MA *y*, at a higher MD Level than MA *x*, and associated with at least one of the VID(s) or the I-SID also in MA *x*, does have a MEP configured on the Bridge Port.

b) **ConflictingVIDs**—MA *x* is associated with a specific VID list or I-SID, an Up MEP is configured on MA *x* on the Bridge Port, and some other MA *y*, associated with at least one of the VID(s) or I-SID also in MA *x*, and at the same MD Level as MA *x*, also has an Up MEP configured on some Bridge Port.

c) **ExcessiveLevels**—The number of different MD Levels at which MIPs are to be created on this port exceeds the Bridge's capabilities (see 22.3).

d) **OverlappedLevels**—A MEP is created for one VID or I-SID at one MD Level, but a MEP is configured on another VID or I-SID at that MD Level or higher, exceeding the Bridge's capabilities (see 22.3).

A Bridge uses detection of the ExcessiveLevels error to refuse an operation on a managed object and thus avoids adding Bridge Ports to the error lists. This is because this incremental operation is known to be the one that exceeds the capabilities of the Bridge. However, a Bridge uses only the detection of the ExcessiveLevels error to refuse an operation on a managed object. That is because the other errors can arise as a result of a management operation, e.g., the deletion of a Static VLAN Registration Entry, that has no

knowledge of CFM and cannot report the error. Furthermore, the root cause of either error might not be the last MA to be configured and could be under the control of another administration. Therefore, management operations that trigger errors other than ExcessiveLevels are performed, not rejected. The lists of Bridge Ports in error are maintained (12.14.4), so that the system administrator(s) can agree on a course of action, outside this standard, to correct the problem.

22.3 MPs, Ports, and MD Level assignment

It is possible to configure MPs at different MD Levels for different VIDs on a single Bridge Port. However, this imposes upon an implementation the burden to be able to configure up to 8189 MD Levels for the VIDs on a Port, 4094 for MHFs and 4095 for MEPs, each requiring 3 bits of storage. An implementation may not support different MD Levels for MIPs on different VIDs on a single Port, hence the ExcessiveLevels and OverlappedLevels error responses (22.2.4). At least one MD Level shall be supported for each port in a Bridge, such that MIPs can operate at that MD Level, and all CFM PDUs below that MD Level are filtered or processed, according to the configuration of MEPs on the port.

In Figure 18-7, the left-most Maintenance Entity at the lowest MD Level (0) has one MEP in the customer's equipment 1 and one in Provider Bridge 2. When Down MEPs are used in this manner to create a Maintenance Entity that interconnects two administrations, those administrations can agree upon a particular MD Level (and MAID and MEPIDs) to use. To enhance the chances for interoperability, the MD Level for Down MEPs should be the lowest not already in use by an existing MA, typically 0.

Assigning MD Levels with gaps between the levels used, as in Figure 18-7, can be wasteful of resources, especially MAC Address Registration Entries in the FDB. Minimizing the number of MD Levels, and concentrating the MD Levels used toward MD Level 0, minimizes the required resources, since CFM PDUs carrying higher MD Levels than those used in a Bridge are treated as ordinary multicasts by that Bridge. However, if one creates a Maintenance Domain at MD Level 0, and subsequently needs a level beneath that one, for example if a PBN is substituted for a physical connection, then the MD Level of the original Maintenance Domain might have to be changed. If there is another Maintenance Domain above the one at MD Level 0, that one would have to be changed, first, and so on. Similarly, if an existing Maintenance Domain at MD Level 3 is partitioned into several Domains, a new Maintenance Domain at MD Level 4 would be needed to ensure end-to-end connectivity across the extent of the old Maintenance Domain.

Such difficulties can be avoided in several ways:

a) The MD Levels of different Maintenance Domains can be insulated from each other by VLAN tags. Appropriate placement of the MEPs in Bridge Ports can ensure that the tags insulate the MD Levels, and that no reconfiguration will be necessary.
b) If it is expected that an additional MD Level will be needed because a physical link will likely become virtualized, MD Level 0 can be left vacant.
c) If it is expected that an additional MD Level will be needed because a Maintenance Domain will likely be partitioned, a gap can be left between that Maintenance Domain's MD Level and the lowest MD Level offered to a customer of that Maintenance Domain.

See J.2 for a description of an MD Level assignment plan that can be used in the most general case.

22.4 Stations and CFM

Stations, as well as Bridges, can implement CFM. For the purposes of CFM, and for no other purposes, a Station is modeled as a Bridge, with the following exceptions:

a) This standard defines no entities above the layer of Down MPs in Figure 22-8. In particular, a Station has no Port filtering entities, Up MPs, or Forwarding Process. A CFM-capable Station is therefore a set of one or more disconnected Bridge Ports.
b) A Station shall not support the creation of MIPs or Up MEPs. Only Down MEPs can be implemented in a Station.
c) CFM PDUs not processed and not discarded by a MEP shall be ignored, and not processed, by the Station.
d) A Station shall create no entries in the Configuration Error List managed object (12.14.4) except for CFMleak errors.

22.5 Scalability of CFM

CFM can create a considerable load on the resources of a Bridge. Ideally, a Bridge has the capability to reflect LBMs as LBRs at line rate, so that the capacity and reliability of a network can be tested. The total load imposed by LBMs, LBRs, LTMs, and LTRs cannot be predicted, as these are all under the control of the system administrator, and any number of streams of these PDUs can be generated.

The load imposed by CCMs is more regular, so reasonable predictions of the load they impose can be made. Based on a figure of 109 octets as the minimum frame size, from the start of the destination MAC address of one frame to the start of the destination MAC address of the next frame,[38] Table 22-3 shows the load that is imposed by CCM transmission and reception upon a Bridge Port with a single configured MEP, as a function of the CCM transmission interval, the number of MEPs in the MA, and the speed of the link. One row in the table shows the number of CCMs per second transmitted or received. The number in each of the other rows is the fraction of the total bandwidth required by those CCMs. Table 22-4 extends this calculation by multiplying all numbers by 1000, for the case where 1000 VIDs, each with a MEP, are configured on the Bridge Port, again with the specified transmission interval and average number of MEPs per MA.

Counting 4094 allowed VIDs in a VLAN tag, three kinds of MEPs, Up VID MEPs, Down VID MEPs, and Down no-VID MEPs, and eight MD Levels, a single Bridge Port with no Link Aggregation can, in theory, support 65 504 MEPs and 8188 MHFs.

Table 22-3—Bandwidth required for CCMs for 1 MA

Transmit interval	**3.3 ms**		**10 ms**		**1 s**		**60 s**	
MEPs in each MA	**10**	**2**	**10**	**2**	**10**	**2**	**10**	**2**
CCM / s	**3000**	**600**	**1000**	**200**	**10**	**2**	**0.167**	**0.033**

22.6 CFM in Provider Bridges

The S-VLAN component of a Provider Bridge is, for the purposes of this standard, an example of a VLAN Bridge. Fortunately, the many combinations possible when configuring CFM on Customer Bridges and Provider Bridges, connected using Port-based, C-tagged, or Remote Customer Service Interfaces (RCSIs), can be simplified.

22.6.1 MPs and C-VLAN components

When a C-VLAN component is integrated into a Provider Edge Bridge to form a C-tagged service interface, there is little justification for making all possible CFM entities manageable. Subclause 15.4 describes a C-tagged service interface, illustrated in Figure 15-4. Figure 22-10 recasts Figure 15-4, illustrating the minimum set of CFM functions that a C-tagged service interface is required to support, if its Provider Bridge supports CFM. Almost all of the CFM components have been removed from the C-VLAN component. As a result, the transformations made in 22.1.2 and 22.1.3 are unnecessary, and the subclause references collapse to match those in Figure 15-4. The S-VLAN component contains almost the full suite of CFM entities. One set of shims has been moved from the CNP to the CEP, however.

The managed objects in 12.14 support the creation of up to eight MEPs below the Bridge Port Transmit and Receive process (8.5). These MEPs belong to MAs associated with no VID. A MEP in this position would be of little use in a CNP, since there is no need to pair it with a MEP in the PEP to protect an Internal LAN. However, a MEP attached to no VID in the CEP could be used to protect the LAN to the customer equipment.

In order to support protection of the CEP's LAN, while maximizing interoperability, whenever (Down) MEPs are created (12.14.6.3) in an MA associated with no VID, a Provider Edge Bridge shall allow those MEPs to be created using the interface number [item d) in 12.14.6.3.2] for a CEP.

22.6.2 Maintenance C-VLAN on a Port-based service interface

Assume that a customer's C-VLAN Bridge is attached to an S-VLAN Bridge as in Figure 22-4, and that the customer wants to pair a Down MEP in the C-VLAN Bridge with a similar Down MEP in the C-VLAN Bridge on the other side of the PBN, thus creating an MA to provide end-to-end protection of the service instance offered by the Provider. In order to obtain the advantage of inserting the CFM PDUs above the

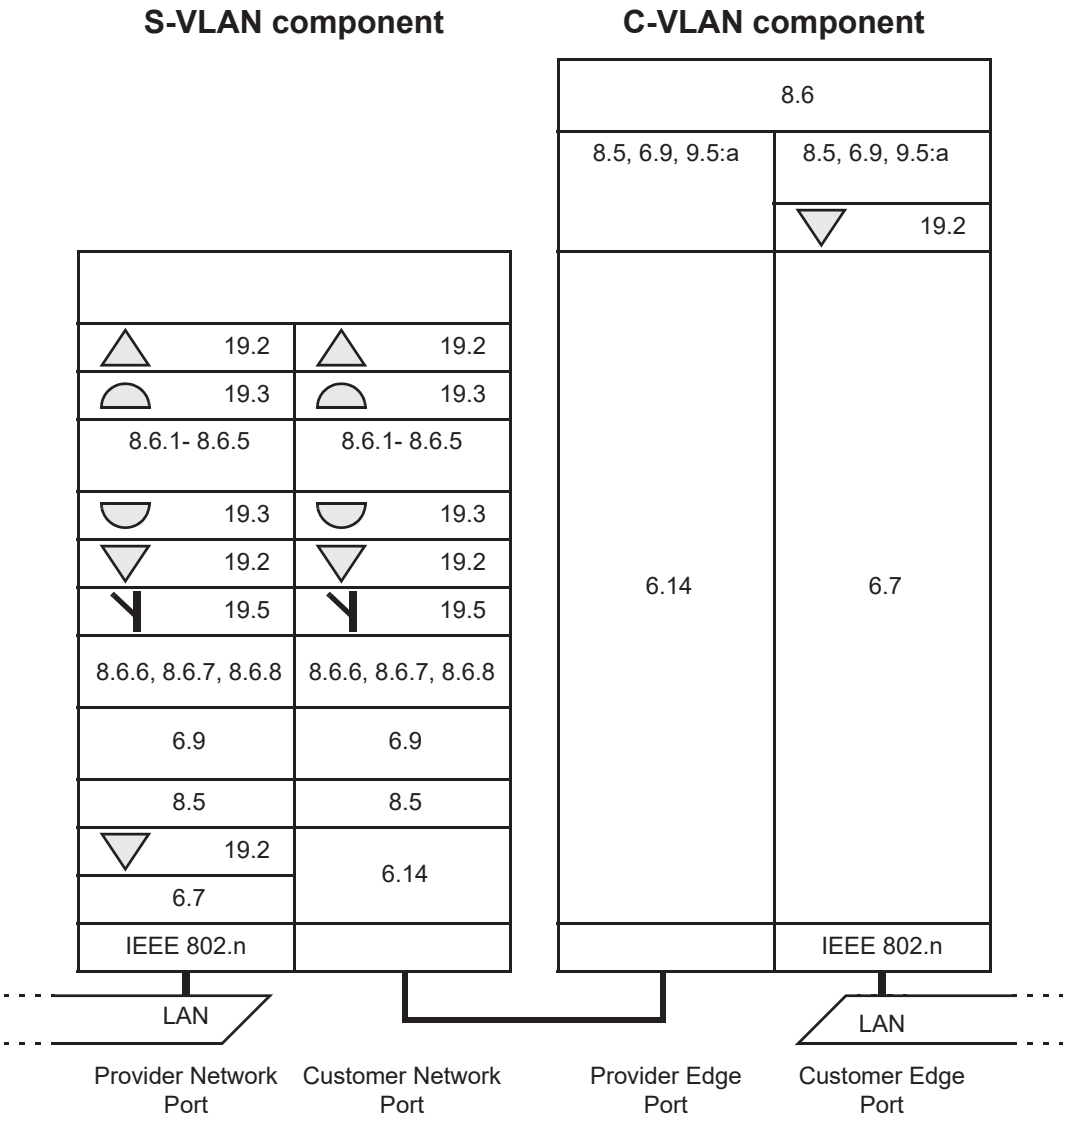

Figure 22-10—CFM in a Provider Edge Bridge C-tagged service interface

Queuing entities, the customer would not use MEPs below the Bridge Port Transmit and Receive process (8.5). The customer could create one MA for each C-VID. However, this would have drawbacks in that:

a) The extra MAs beyond the first MA would provide very little protection on a Port-based service.
b) Each extra MA would add to the overhead of CFM PDUs.
c) The C-tagged CFM PDUs would not be detected by any of the CFM entities in any Provider Bridge, so no MIPs would be present in the customer's MAs.

If the customer, instead, creates an MA on only one C-VLAN, the Maintenance C-VLAN, and configures the two C-VLAN Bridges to pass the Maintenance C-VLAN across the PBN untagged, then:

d) The service instance is protected.
e) The provider can configure a MIP on the S-VLAN carrying the customer's service instance that is visible in the customer's MA.

22.6.3 Maintenance C-VLAN on a C-tagged service interface

Assume that a customer's C-VLAN Bridge, illustrated by Figure 22-4 (less, of course, the box for "Support of the ISS for attachment to a PBN (6.13)"), is attached to a Provider Edge Bridge as in Figure 22-10. Assume that the customer has purchased several service instances, which have C-tagged service interfaces to other of the customer's C-VLAN Bridges at several different locations. Let us further suppose that the customer wants to pair Down MEPs in the C-VLAN Bridge to create MAs to provide end-to-end protection of the service instances. In order to obtain the advantage of inserting the CFM PDUs above the Queuing entities, the customer would not use MEPs below the Bridge Port Transmit and Receive process (8.5). The customer could create one MA for each C-VID.

There would be more justification in creating an MA per C-VLAN than for the Port-based service instance described in 22.6.2. However, if the customer is reasonably confident that the provider will carry each C-VLAN in the correct S-VLAN, then the customer can create multiple Maintenance C-VLANs, one per provider service instance (S-VLAN), and thus one per PEP in the C-VLAN component. By configuring each of these PEPs to pass that one C-VLAN untagged to the corresponding CNP in the S-VLAN component, the CFM PDUs in that one customer MA are visible to the S-VLAN component. The provider can configure a MIP for that S-VID that is visible to the customer's MA. The customer can have one MA protecting each service instance.

22.6.4 MPs and Port-mapping S-VLAN components

When a Port-mapping S-VLAN component is used to provide RCSIs there is little justification for making all possible CFM entities manageable. The other Provider Bridge components can provide the necessary MPs for service OAM. There is one MP that can only be provided by the Port-mapping S-VLAN component and that is the point below the Bridge Port Transmit and Receive process (8.5) on the RCAP. This MP can be used to protect the LAN to the neighboring PBN.

Figure 22-11 extends Figure 22-10, showing the minimum set of CFM entities required for a C-tagged RCSI, if the Provider Bridge supports CFM. The S-VLAN component and C-VLAN component support the same set of CFM entities as in Figure 22-10. The Port-mapping S-VLAN component that provides the RCSIs supports at least one more CFM entity, as shown, that can protect the LAN to the neighboring PBN.

Similarly, in the case of a Port-based RCSI or an internal PNP the required service CFM entities can be provided by the S-VLAN component. Thus the only CFM entity required from the Port-mapping S-VLAN component is the one shown in Figure 22-11 which is independent of the number and type of internal Ports provided.

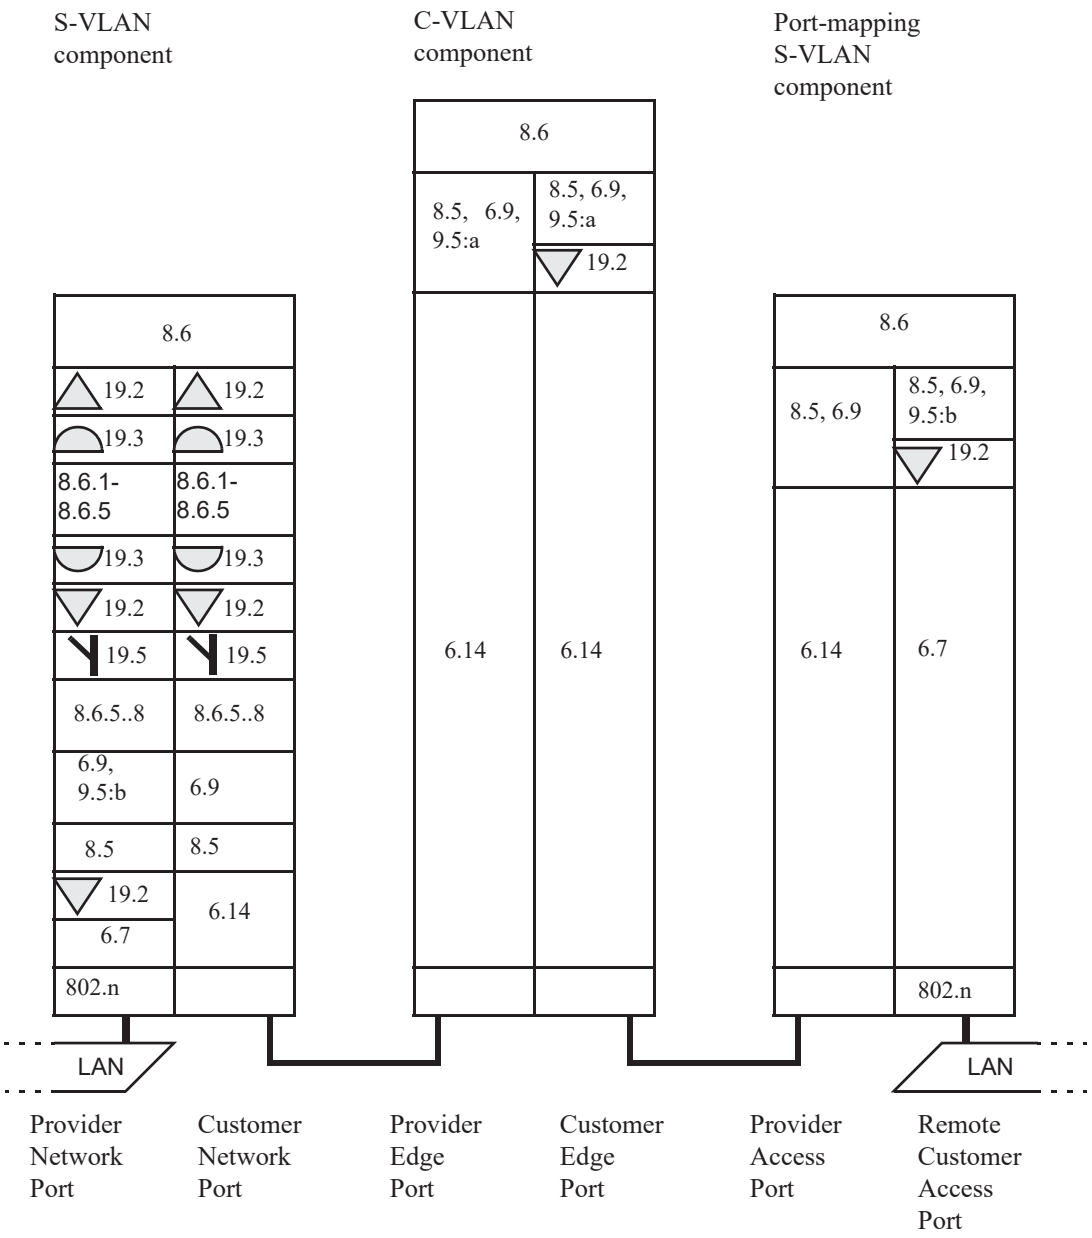

Figure 22-11—CFM in a Provider Edge Bridge C-tagged RCSI

22.7 Management Port MEPs and CFM in the enterprise environment

Figure 22-12 illustrates the placement of Management Port MEPs. It is similar to the CFM Port illustrated in Figure J-1. However, the Management Port MEPs are configured explicitly for the Management Port. They do not represent information for any other Bridge Port in their CFM PDUs. Therefore, there is only one MEP for each MA. Furthermore, there can be no MHFs configured on a Management Port, because there can be no MEP further along the path to terminate the MA.

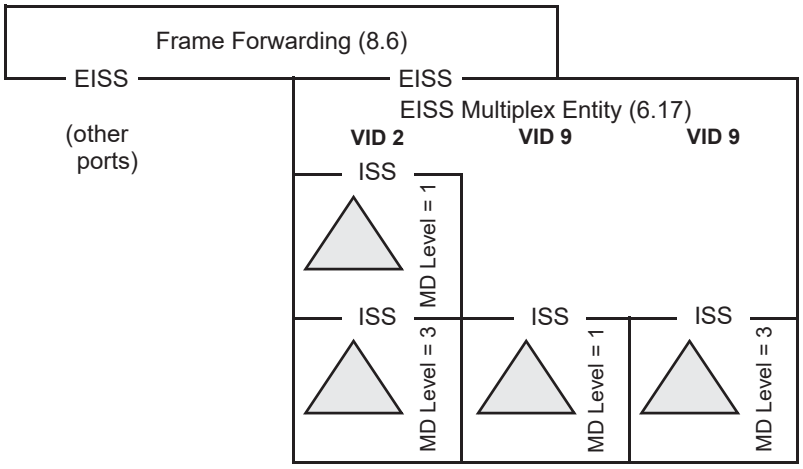

Figure 22-12—Up MEPs in a Management Port

NOTE—The fact that a CFM Port could be configured on a Management Port, and thus instantiate MHFs on the Management Port, does not contradict the preceding paragraph. Those MHFs are configured on a Bridge Port, and instantiated on the Management Port (CFM Port), not configured on the Management Port.

Although this standard uses the terminology of Provider Bridges and describes the functions of CFM in terms of Provider Bridges, it can be applied to any Bridge, whether a Provider Bridge, C-VLAN Bridge, or MAC Bridge. The normative definitions and functions specified by this standard do not depend on, for example, whether the VLAN tag used to associate frames with VLANs use the customer format or the provider format. Certainly, no business relationships are required to implement this standard.

Given that both the users and the providers of an enterprise network are, by definition, all members of the same company, the utility of CFM in the enterprise environment is less than in the provider/customer environment. The network administrator of an enterprise network can find a number of uses for CFM, however.

The default values for MEP and MIP configuration make CFM easy to configure for the typical enterprise network. Figure 22-13 illustrates two Bridge Ports, the Management Port, and one Bridge Port connected to a LAN, using the default configuration as follows:

a) A single Maintenance Domain can be configured at MD Level 0.
b) An MA for each VID is configured in each Bridge.
c) A single MEP for each VID is configured on a Management Port in each Bridge. Typically, this is a port with no external interface, often the one used to manage the Bridge.
d) Through the Maintenance Domain managed object previously created, it is easy to define a MIP on every Bridge Port on every VID.

This simple configuration enables the administrator to use LBMs and LTMs to diagnose network faults among the Bridges of the network. In addition, specific high-priority VLANs, e.g., a VLAN interconnecting key routers and file servers for a large enterprise, could be explicitly monitored via CFM.

In a large enterprise, separate Maintenance Domains can be established, along with an accompanying enterprise-wide Maintenance Domain at a higher MD Level, in order to define and enforce separate spheres of responsibility for separate network administrations, e.g., in different departments in a university. The boundaries between Maintenance Domains might well coincide with administratively imposed boundaries between MSTP Regions.

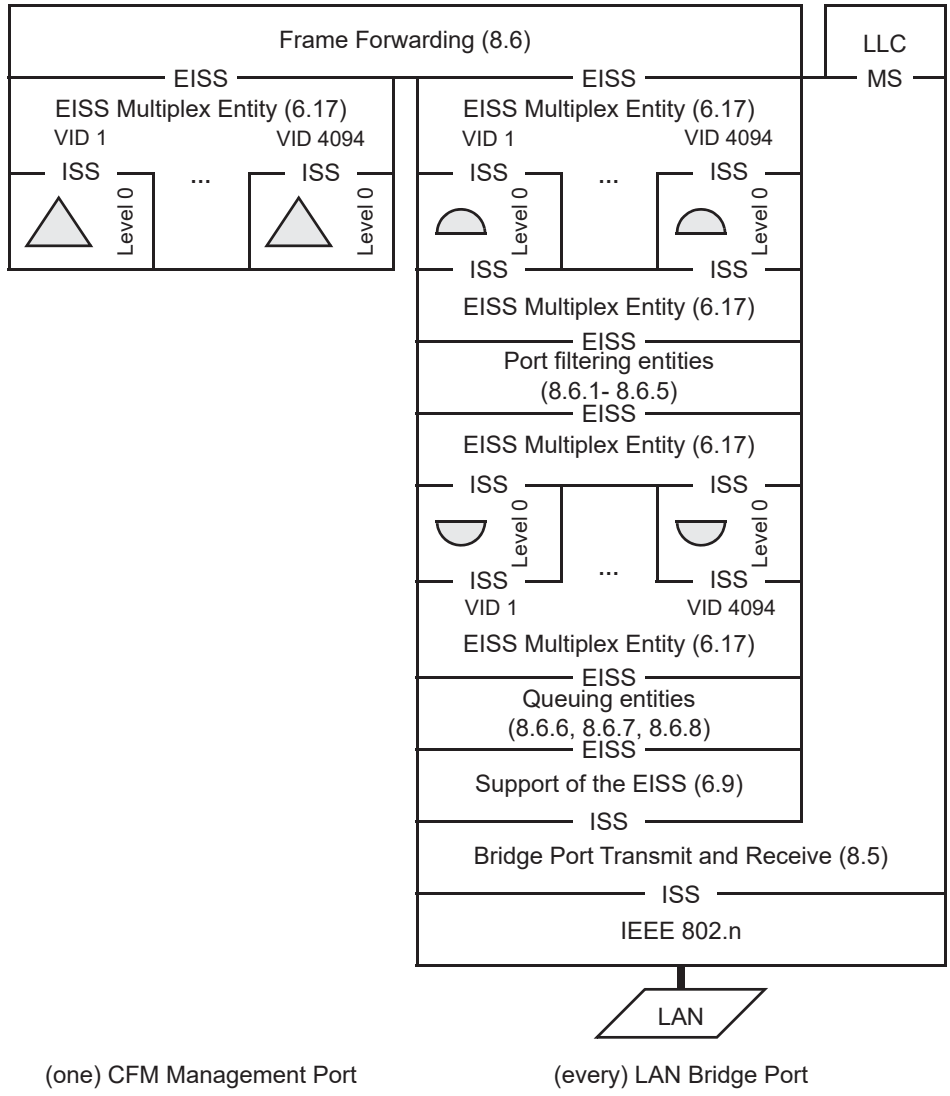

Figure 22-13—CFM in the enterprise environment

22.8 Implementing CFM on Bridges that implement earlier revisions of IEEE Std 802.1Q

It might or might not be easy to implement CFM in a VLAN Bridge that implement earlier revisions of IEEE Std 802.1Q. The problems are best illustrated by a three-port Bridge as illustrated in Figure 22-14. Each of the three Bridge Ports A, B, and C is configured with MEPs and MIPs at the MD Levels shown in the figure.

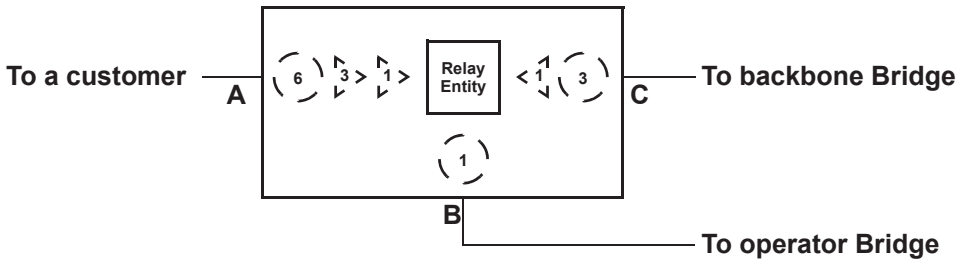

Figure 22-14—CFM in the enterprise environment

If a CCM at MD Level 3 enters the Bridge from Bridge Port C, that CCM will be passed to both of the other Bridge Ports A and B. It will not exit Bridge Port A, however, because there is a MEP at MD Level 3 on that Bridge Port. It will, however, pass through Bridge Port B to the other operator Bridge. One can easily imagine configuring MAC Address Registration Entry in the Bridge for the MD Level 3 group address shown in Table 8-18 that permits that group address to pass through the Bridge Ports B and C, but not through Bridge Port A, and also sends the CCM to a CFM module in the Bridge's Higher Layer Entities, perhaps residing on the Management Port of 22.7, for processing. It is precisely so that MAC Address Registration Entries can be used in this manner that CCMs and LTMs are required to use the group addresses in Table 8-19 and Table 8-18.

A potential problem for some implementations can be seen if readers ask what happens if that same CCM at MD Level 3 enters from Bridge Port A. In that case, the CCM does not exit either of Bridge Ports B or C, because Bridge Port A has a MEP at MD Level 3 to stop it; MAC Address Registration Entries prevent frames from leaving a Bridge Port, not from entering one. Many Bridges have the ability to filter incoming frames based on the destination MAC address and/or the contents of the frame; either facility will enable this CCM to be stopped. In order to support both a Down MEP attached to no VID, and a Down MEP attached to a tagged VID at a lower MD Level than the no-VID MEP, the Bridge filters frames based on both the MAC address and whether the frame is tagged.

23. MAC status propagation

Individual LANs, each operating its own MAC and media access method-specific procedures, can be connected by one or more TPMRs to form a composite LAN that is transparent to other Bridges and stations and their configuration protocols. The MAC Status Protocol (MSP) ensures that changes in the connectivity provided by the composite LAN results in changes in the MAC_Operational status parameter (IEEE Std 802.1AC) at each of the attached Bridges and stations, just as if they were connected to an individual LAN.

NOTE 1—MSP is designed only for use with point-to-point LANs.

MAC_Operational provides rapid notification of connectivity failures and prompts the necessary initial protocol behavior to ensure that new connectivity has not caused an instantaneous data loop. If this MAC status parameter were not propagated by a TPMR, Bridge protocols would have to rely on periodic transmissions to detect connectivity changes. On their own these periodic transmissions take longer to detect failures, and cannot detect the possibility of data loops until they have been created, as illustrated by the following examples.

Figure 23-1 shows a TPMR connecting two Bridge Ports.

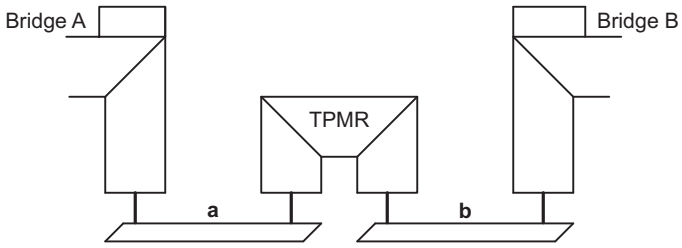

Figure 23-1—TPMR connecting two Bridge Ports

Assume that Bridge A is the spanning tree Designated Bridge for the LAN that comprises the individual LANs **a** and **b** and the TPMR, and that Bridge B's spanning tree Root Port is shown. If **a** fails and the TPMR does not propagate MAC_Operational, Bridge B will not reselect its Root Port until it has timed out the last BPDU from A.

Figure 23-2 shows a link that uses two TPMRs, perhaps because LAN **c** uses a non-IEEE-802 technology together with an appropriate convergence function.

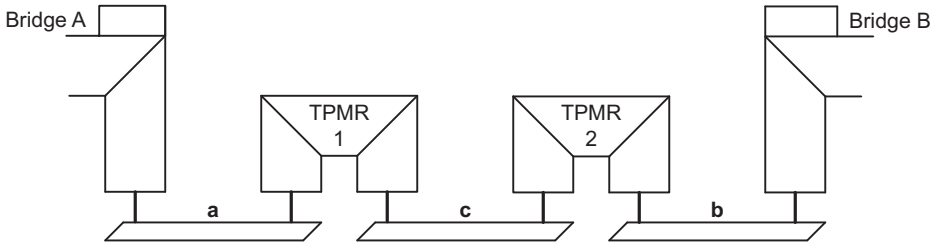

Figure 23-2—TPMR chain connecting Bridge Ports

Without MAC_Operational propagation, failure of **c** will not be immediately visible to either Bridge. Worse, if **c** fails and is restored after a while, both A and B will believe themselves to be Designated Bridge for the composite LAN, and will forward frames until one receives a BPDU from the other, even if a data loop has been created.

When working correctly the MAC Service provides bidirectional connectivity or no connectivity at all. MAC_Operational is TRUE for each of two peers connected to the same LAN if they can communicate, and FALSE for either or both if they cannot. Protocols, such as the spanning tree protocols, that make use of MAC_Operational to detect new connectivity and initialize state machines rely on the last peer that sees MAC_Operational transition TRUE to enforce any necessary behavior after a connectivity change. For example, it is the last of two connected Bridge Ports to be powered on that enforces the necessary delay prior to setting operEdge TRUE (13.27).

NOTE 2—MAC_Operational being TRUE within a single station does not guarantee connectivity to any peer. Even if connected by a point-to-point LAN, the peer could have just reinitialized. It is not possible, given only the use of the LAN medium for communication, to arrange for two peers to transition MAC_Operational at exactly the same time.

This clause defines media-independent propagation of MAC status between TPMRs and to attached stations, as follows. It:

a) Models MAC status propagation within the Bridge architecture used to describe a TPMR (23.1).
b) Provides an overview of MSP (23.2).
c) Specifies state machines for MSP operation (23.3–23.9).
d) Specifies the addressing, protocol identification, format, encoding, and validation of MAC Status Protocol Data Units (MSPDUs, 23.13–23.16).

The term *MAC status propagation* (3.154) describes the overall process of communicating a MAC_Operational parameter value through one or more TPMRs. MSP can use *link status notification*[39] (3.123) between some Bridges and end stations and *MAC status notification* (3.153) between others. These two notification methods differ, as follows:

e) Link status notification uses frames to convey information about MAC_Operational. It does not interrupt or prevent other communication between adjacent Bridges. However, it requires both the source and destination of the notification to implement additional protocol. Since it does not prevent communication it cannot, by itself, prevent loops caused by new connectivity.
f) MAC status notification uses a layer management interaction with the local MAC Entity to change MAC_Operational for a peer user of the MAC Service provided by an individual LAN. It is equivalent to bringing a link down, and is generally effective for MACs with specific point-to-point support. It also interrupts all other communication, including the use of in-band management to rectify an underlying problem.

Where management of a TPMR is permitted through one of its ports, the failure of an individual LAN not in the communication path does not cause MAC status propagation to prevent management connectivity. In Figure 23-2, for example, the failure of LAN **b** does not prevent connectivity to TPMR 2 from Bridge A. When **b** recovers, MAC_Operational for Bridge A's Port is "blipped," i.e., taken FALSE for a brief period and allowed to return TRUE, thus meeting the requirement for transition when connectivity changes.While this slows the recognition of newly available connectivity, that is rarely an issue since several seconds hysteresis should be applied to any MAC_Operational status transition to prevent higher layer protocols "flapping."

[39] The use of the term link status notification in this standard is not to be confused with the term used in SNMP to refer to a type of trap notification.

23.1 Model of operation

The model of operation presented in this clause allows the description of MSP functionality to be consistent with that of the general Bridge architecture and operation (8.2, 8.3). Implementations of a TPMR may adopt any internal model of operation compatible with the externally visible behavior specified.

The additional entities that model MSP operation, and their relationship to the other processes and entities that model the operation of a TPMR are illustrated in Figure 23-3. They comprise the following:

a) A MAC Status Shim (MSS, 23.1.1) for each Port, which allows MSP to control the value of MAC_Operational presented to the TPMR Port connectivity function (8.5.2) and hence to the frame transmission and reception functions of the MAC Relay Entity, Higher Layer Entities, and MAC Status Propagation Entity (MSPE).

b) The MSPE, which implements MSP, controlling each MSS to ensure that frames are not forwarded by the MAC Relay Entity until status propagation is complete, transmitting and receiving frames to support link status notification, and controlling the individual LAN's MAC to provide MAC status notification.

NOTE—In a TPMR the priority signaling functions shown in Figure 23-3 are provided by 6.20 Support of the ISS with signaled priority.

MSPDUs are sent to a standard group address. They are received by the MSPE, but are forwarded by the MAC Relay Entity (like any other frame) in order to communicate without a delay in each TPMR. The MSPE attaches to each Port by a TPMR Port connectivity function (8.5.2) that allows it to transmit to and receive from the attached individual LAN only, as shown in Figure 23-3.

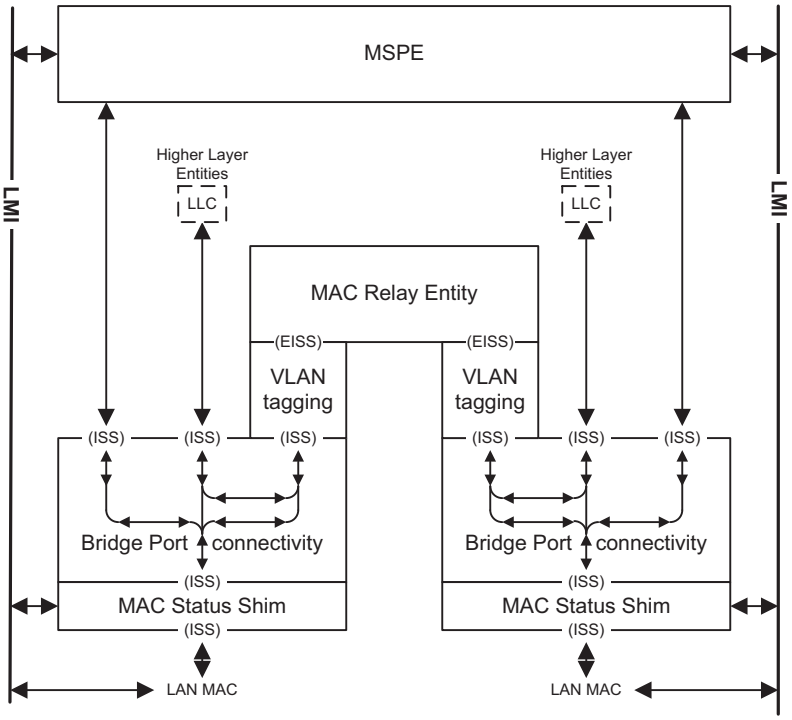

Figure 23-3—MSSs and the MSPE

23.1.1 MAC Status Shim (MSS)

The MSS allows MSP to control the transmission and reception of frames through a Port by all the entities (including the MAC Relay Entity) supported by the TPMR Port Connectivity function (8.5.2). Each transmit request from the latter at the MSS's upper ISS-SAP results in a corresponding transmit request at the lower ISS-SAP supported by the LAN MAC and each receive indication from the lower ISS-SAP results in a corresponding receive indication at the upper ISS-SAP, without omission or duplication, and with identical parameters, if and only if MAC_Operational for the upper ISS-SAP is TRUE.

The values of the MAC status parameters presented at the upper ISS-SAP are determined as follows:

— **MAC_Enabled**: The value of this parameter is FALSE if the value of STM's disableMSS variable is TRUE. Otherwise, the value of this parameter is TRUE. STM communicates the value of its disableMSS variable using a Layer Management Interface (LMI).
— **MAC_Operational**: The value of this parameter is TRUE if and only if the MSS's MAC_Enabled parameter is TRUE and the value of the MAC_Operational parameter provided by the LAN MAC at the lower ISS-SAP is TRUE.

The MSPE uses the LMI to control and receive status from each MSS and individual LAN MAC, allowing generic management requests and indications to be tailored to the requirements of different MACs, as well as providing a way for one MSS to propagate status to another (via the MSPE), even though MAC_Operational for the MSS's upper ISS-SAP is FALSE.

23.1.2 Relationship of CFM to the MSS

MEPs may be placed above or below the MSS. A MEP placed in the lower position and partnered with another MEP so that the pair spans a chain of TPMRs would obscure the LAN MAC's MAC_Operational parameter and interfere with the operation of MSP. For this reason, MEPs that protect individual LANs should be placed below MSS, and MEPs that protect chains of TPMRs should be placed above MSS.

23.2 MAC Status Protocol (MSP) overview

This clause provides examples of MSP operation as time sequence diagrams that show the following:

a) Exchange of MSPDUs transmitted and received to support link status notification.
b) The values of MAC_Operational and MAC_Enabled provided by the following:
    1) Each MSS, at its upper ISS-SAP, to the TPMR Port connectivity function.
    2) Each LAN MAC to the MSS, at the latter's lower ISS-SAP.

The value of MAC_Operational provided by the MSS is TRUE if, and only if the MSS' MAC_Enabled is TRUE and the value of MAC_Operational provided to the MSS by the LAN MAC is TRUE. The latter can be TRUE only if MAC_Enabled is TRUE for both the LAN MAC and its peer in the other station connected to the LAN. The MSPE can use the LMI to disable the MSS in order to prevent communication until MAC status propagation has occurred, and to disable the LAN MAC in order to provide MAC status notification to a peer service user. This clause uses the symbols defined in Table 23-1 to show combinations of the MAC status parameter values for each Port.

Table 23-1—Time sequence diagram symbols

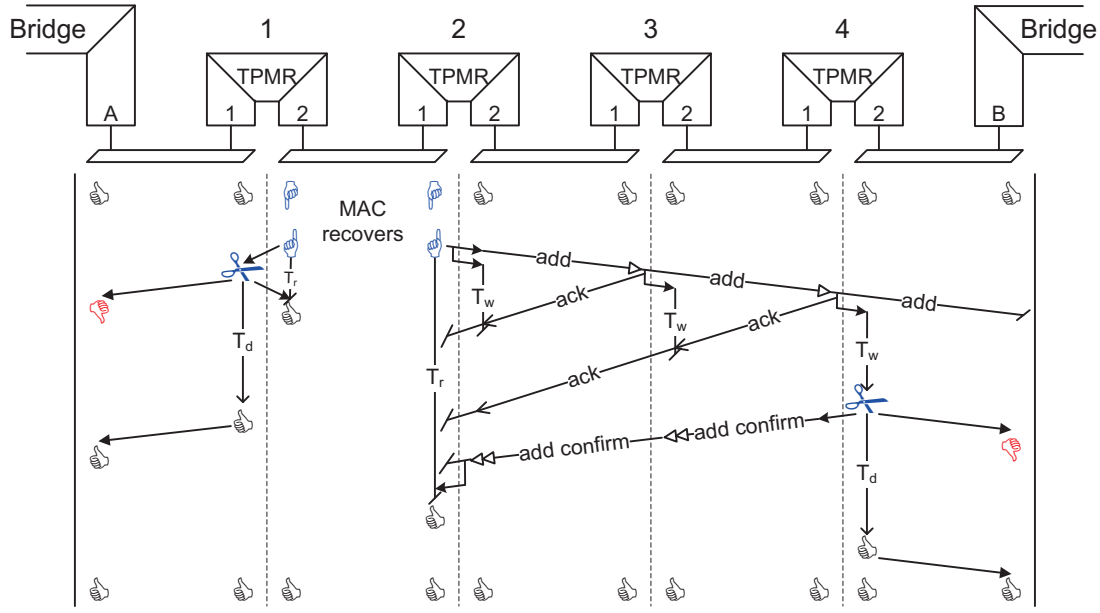
MSS	**MAC_Operational**	T	F	F	F	F
	MAC_Enabled	T	T	F	F	—
LAN MAC	**MAC_Operational**	T	F	F	T	F
	MAC_Enabled	T	T	T	T	F

T = TRUE, F = FALSE, — = either TRUE or FALSE

Throughout this protocol description, the term *LAN* is used to refer to individual LANs connecting adjacent TPMRs or a TPMR and an adjacent Bridge. A *chain* is a series or part of a series of TPMRs connected by LANs, and a *link* is the connectivity provided by a chain between non-TPMR devices that communicate at a higher (sub) layer and perceive the entire link as a single transparent LAN.

The number of TPMRs in the following examples is deliberately high, four where one or two might be more common, in order to show all the necessary aspects of protocol behavior.

Signaling the addition of new or restored connectivity is considered first, as it is more difficult than signaling failure. Figure 23-4 shows the response to a new or recovered LAN connection in a link between two Bridges that do not implement MSP—and thus require MAC status notification.



Timers: Tr : linkNotifyWhen (‘retry timer’) Tw : macNotifyWhen (‘wait timer’) Td :macNotifyWhile (‘down timer’)

Figure 23-4—Adding connectivity

Before the LAN that connects TPMR 1 to TPMR 2 is MAC_Operational, each MSPE disables its MSS ( ). This allows the MSPE to intercept the new connectivity as the LAN MAC asserts MAC_Operational ( ). TPMR 2 propagates the new status to its other Port, transmitting an *add* MSPDU. TPMR 2 does not necessarily know that TPMR 3 implements MSP (or indeed is a TPMR) but uses the default MSP

configuration—waiting before resorting to MAC status notification and starting a linkNotifyWhile timer (as do TPMRs 3 and 4) on receipt of the *add* (which is forwarded by the Relay Entity). Each TPMR responds to the *add* with an *ack* that clears the timer, but the Bridge at the end of the chain does not (as it does not implement MSP). When TPMR 4's timer expires, its MSPE disables the LAN MAC (✂), ensuring that MAC_Operational becomes FALSE (👎) for the Bridge's Port, and starts a macNotifyWhile timer. When that timer expires, the MSPE reenables the LAN MAC so that the Bridge Port's MAC_Operational can become TRUE (👍) once more. As well as disabling the LAN MAC for its Port 2, TPMR 4 also transmitted an *add confirm* through Port 1, and receipt of this *add confirm* by TPMR 2 causes the latter to cancel its retry timer (linkNotifyWhen). The initial value of macNotifyWhile (MacNotifyTime) is sufficient for the *add confirm* to reach the TPMR 2, and for that TPMR's MSPE to enable the MSS, thus ensuring that there is connectivity between the Bridges connected by the link when they have both reported MAC_Operational TRUE to their local protocol clients.

In Figure 23-4 the MSP configuration of TPMR 2's Port 2 differs from that for Port 1 of TPMR 1. The latter is explicitly configured to use MAC status notification immediately without waiting to see if its peer implements MSP.

Figure 23-5 illustrates the operation of MSP when the connectivity provided by an individual LAN is lost. The MSPE for each of the TPMR ports directly attached to the failed LAN begins by disabling the MSS for that Port (👎) to ensure that connectivity does not 'flap'. Otherwise, the protocol proceeds as for connectivity addition, except that *loss* and *loss confirm* are used instead of *add* and *add confirm*, and the MSSs attached to the failed LAN are left disabled. The final state of the link components is the initial state assumed in Figure 23-4—both attached Bridges have seen MAC_Operational transition to indicate that the connectivity has changed, and the TPMRs in each of the two chains can be reached and managed (if their individual configuration permits) through the attached Bridge Ports.

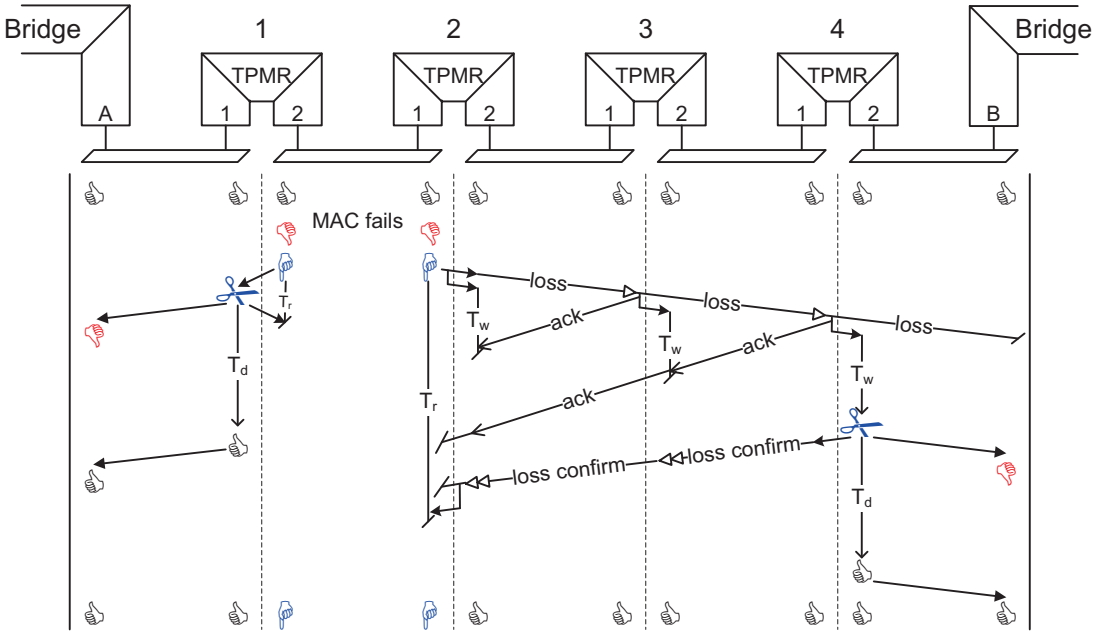


Figure 23-5—Losing connectivity

In the examples above, if an *add*, or *loss* is lost then the TPMR Port that transmitted or relayed that MSPDU will revert to using MAC status notification, as will a TPMR that fails to receive the *ack* from the next (or a subsequent) TPMR in the chain. If the MSPDU is lost on a LAN removed from the TPMR that initiated the link status notification, then that notification will be retried on expiry of the linkNotifyWhen timer, which also serves to protect against the loss of an *add confirm* or *loss confirm*.

Loss of a frame due to physical corruption is rare in LAN technologies, and frame losses due to buffer overrun are not expected when connectivity is being added (as the link is not usable prior to the addition) nor when a loss of connectivity is being signaled (as that connectivity loss will have prevented other frames from being added to the link). The loss of an MSPDU is most likely to be due to failure of one of the LANs, or to interruption of a TPMR's relay functionality by another MSS whose MSPE is also waiting for confirmation that a connectivity change that it has detected has been propagated to the end of the link. MSP does not, and cannot, ensure that information about each and every connectivity change reaches both ends of the link. Unless link status notification or MAC status notification is disabled or the individual LANs fail to report MAC_Operational correctly, MSP does ensure that any change in connectivity is accompanied by one or more notifications at each end of the link, and that a continuous period during which MAC_Operational is reported TRUE at both ends of the link provides unchanged connectivity from 1 second after the start of the period to 1 second before the end. This guarantee meets the requirements implicit in the initial transmission and retransmission strategies of well designed protocols. Protocol clients of the MAC Service should not use the difference between *loss* and *add* MSPDUs to take different actions on receipt, though the distinction can be useful to a network administrator when investigating connectivity changes.

Figure 23-6 provides a common example of simultaneous change. TPMR 2 is powered on and initializes both its ports. When the LAN MAC becomes operational, each Port attempts to send a notification through the other, but cannot as they are both waiting for the connectivity addition to be confirmed. However, in this eventuality, each Port can provide the other with the confirmation required, because the peer system for each of the individual LANs will also have seen the initial MAC_Operational transition and will have initiated a notification toward its end of the link.

NOTE—The SNM state machine transition direct from SNM:LINK_NOTIFICATION to SNM:MAC_NOTIFYING supports this behavior (see Figure 23-11).

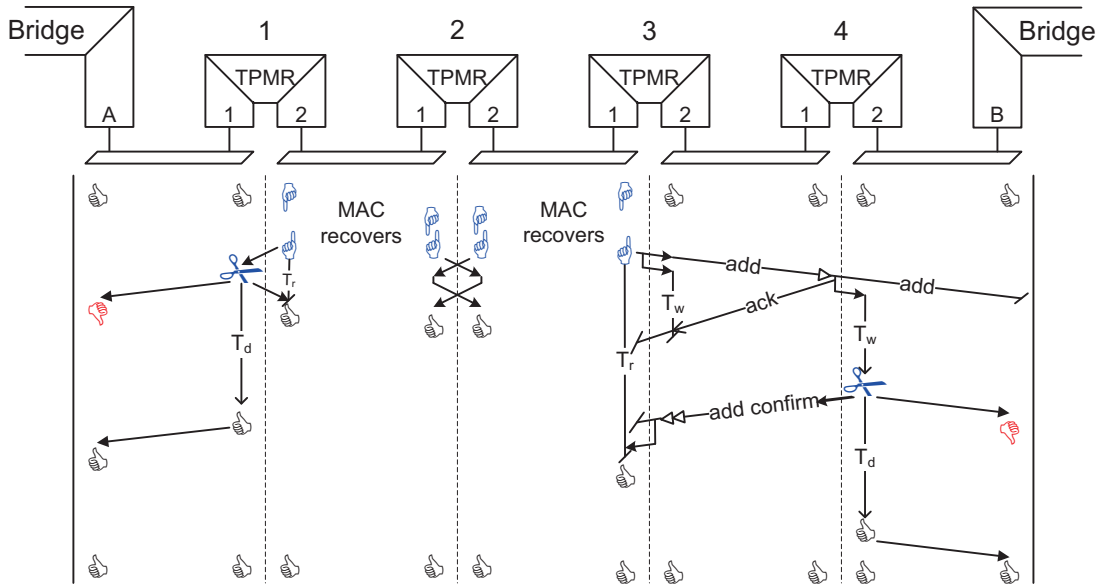

Figure 23-6—TPMR recovery

If the individual LAN that recovers (or loses) connectivity is at the end of the link, MSP ensures that the other end of the link is also aware of the status change as illustrated in Figure 23-7. This figure also shows the effect on MSP of including two nonstandard relays in the chain. Provided they (and their attached LANs) never fail, MSP can continue to operate as intended.

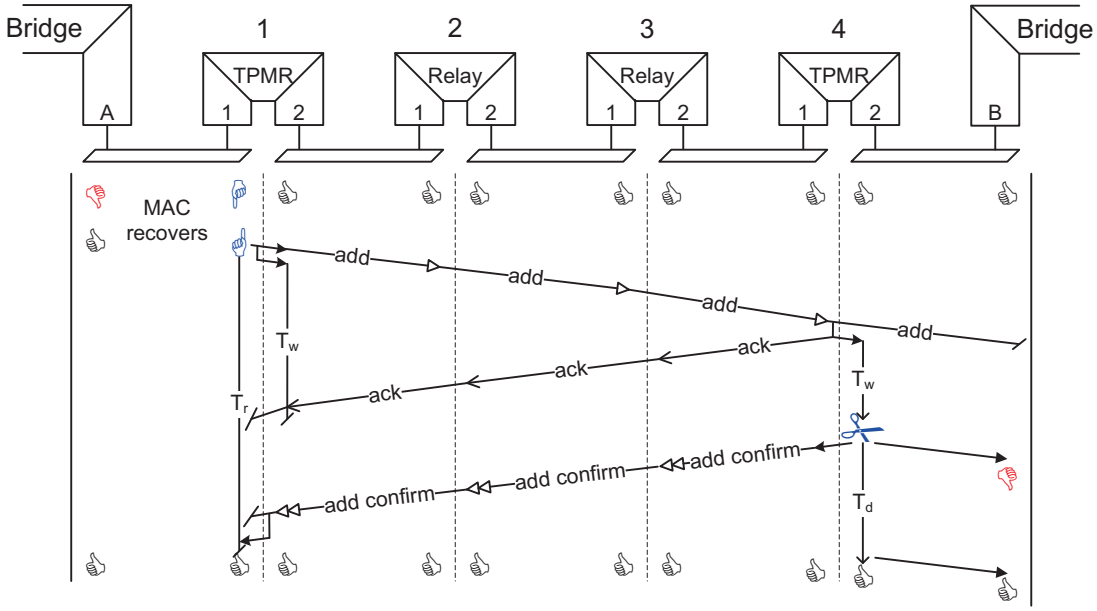

Figure 23-7—Notification from one end of the link to the other

If TPMR 4 is configured to use MAC status notification immediately, it does not return an *ack* as the *add confirm* can be sent almost immediately (see Figure 23-8).

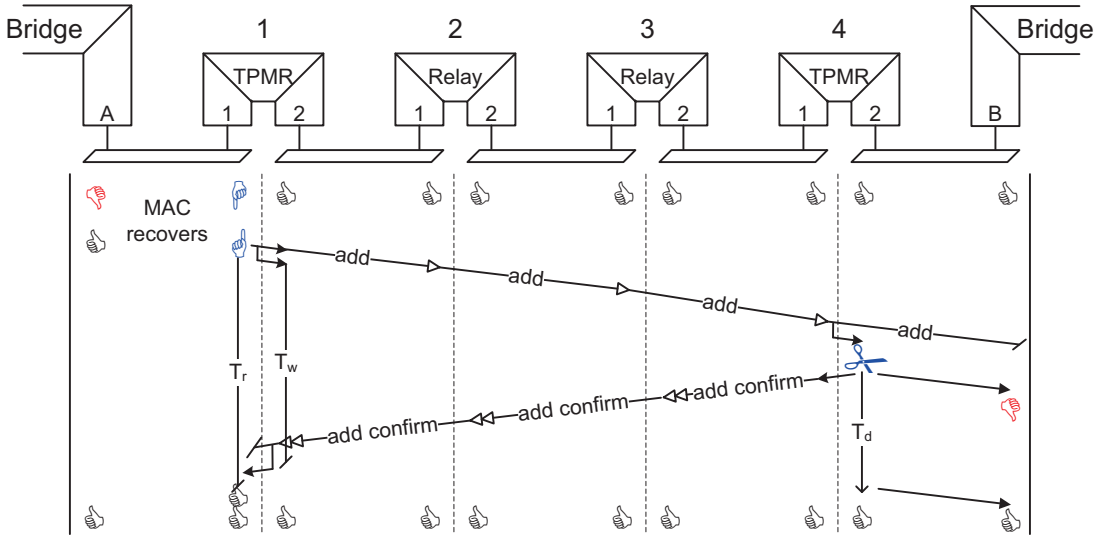

Figure 23-8—Immediate MAC status notification at the end of a link

23.3 MSP state machines

The operation of the MSPE is represented by an instance of each of the following for each Port of the TPMR:

a) A Status Transition state machine (STM, 23.8)
b) A Status Notification state machine (SNM, 23.9)
c) A Receive Process (23.10)
d) A Transmit Process (23.11)

Figure 23-9 shows the state machine variables that are used to communicate between these machines and processes, and that support management control over their operation. Variables prefixed with 'r.' are those of the corresponding state machines of the other Port of the TPMR.

The notational conventions used in Figure 23-9 and in the specification of the state machine are identical to those used in the specification of MSTP (Clause 13) and RSTP and are defined in Annex E.

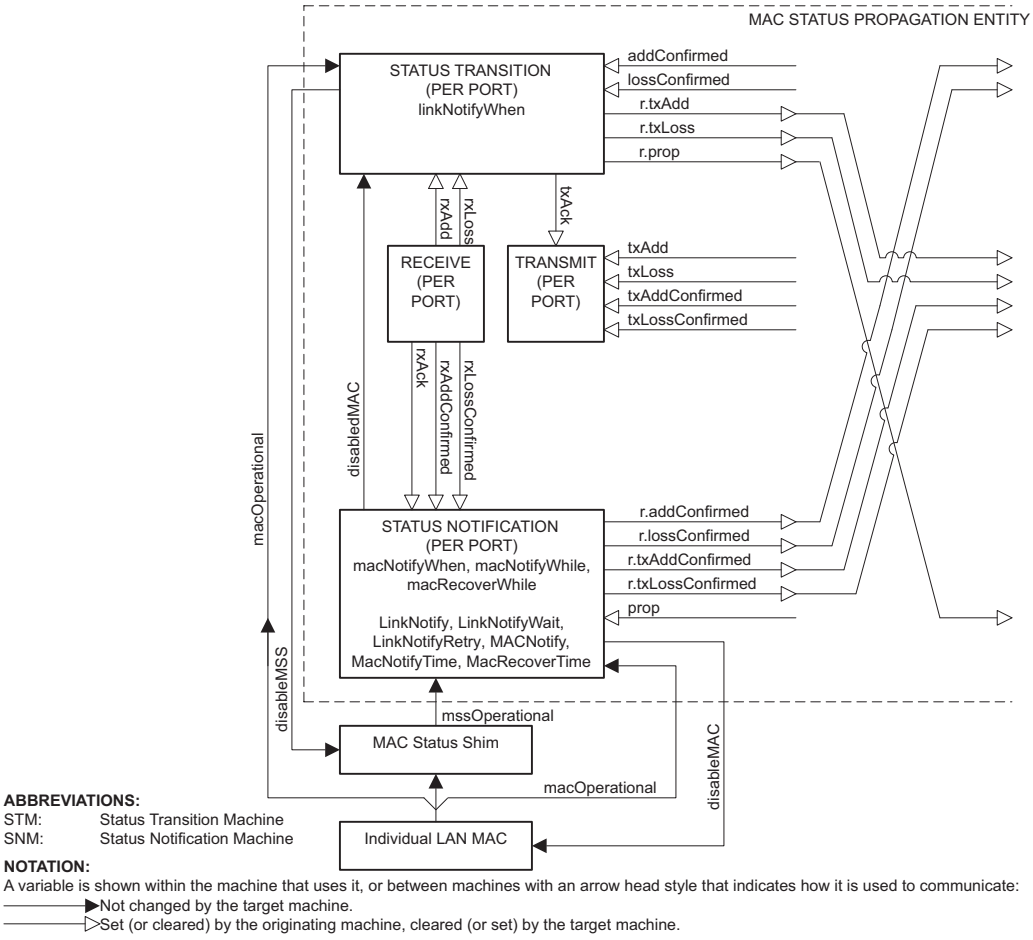

Figure 23-9—MSPE state machine overview

Port 1's STM monitors MAC_Operational transitions for its own LAN, and tells Port 2's Transmit process to send *add* or *loss* link notifications and Port 2's SNM to monitor the progress of status notification, using MAC status notification if necessary. Port 2's SNM receives the *ack* that indicates that it should wait for link status notification to complete, and the *add confirm* or *loss confirm* that indicates that completion. Whether

link status or MAC status notification is used, Port 2's SNM tells Port 1's STM when the notification has been confirmed, so the latter does not have to retry the notification. Port 1's SNM provides the same service to Port 2's STM.

A *loss* or *add* notification that is received from Port 1's own LAN is handled by its STM, which propagates the notification to Port 2's SNM (in the same way as a local MAC_Operational transition) while transmitting an *ack* on Port 1's LAN. Similarly Port 2's STM transmits an *ack* for a link status notification received on its own LAN, and propagates the notification to Port 1's SNM.

23.4 State machine timers

Timers are implemented by variables that are decremented on each timer tick, with timer expiry occurring when they reach zero.

23.4.1 linkNotifyWhen

Causes a link status notification to be sent on each expiry until the original status transition is confirmed.

23.4.2 linkNotifyWhile

Started when a change is first propagated through the Port, on expiry allows MAC status notification.

23.4.3 macNotifyWhile

Sets the time for which the MAC is disabled for MAC status propagation.

23.4.4 macRecoverWhile

Sets the time for which the MAC is permitted to be nonoperational, after being disabled, before the link is reported as lost.

23.5 MSP performance parameters

These parameters are not modified by the operation of MSP but are treated as constants by the state machines. They can be managed independently for each TPMR Port—default values and permissible ranges are specified in Table 23-2.

Table 23-2—MSP performance parameters

Parameter	Recommended or default value	Permitted range
LinkNotify	TRUE	TRUE or FALSE
LinkNotifyWait	0.4 s	0.2–1.0 s
LinkNotifyRetry	1.0 s	0.1–1.0 s
MACNotify	TRUE	TRUE or FALSE
MACNotifyTime	0.2 s	0.01–0.5 s
MACRecoverTime	0.1 s	0.02–0.5 s

23.5.1 LinkNotify

TRUE if the Port uses link status notification to propagate MAC status, and will wait to allow link status notification to succeed before using MAC status notification.

NOTE—If LinkNotify is FALSE, the TPMR still forwards *loss* and *add* notifications transmitted by other TPMRs prior to using MAC status notification, but the TPMR will not originate link status notifications.

23.5.2 LinkNotifyWait

The initial value of the linkNotifyWhile timer.

23.5.3 LinkNotifyRetry

The initial value of the linkNotifyWhen timer of the other TPMR Port.

23.5.4 MACNotify

TRUE if the Port uses MAC status notification.

23.5.5 MACNotifyTime

The initial value of the macNotifyWhile timer.

23.5.6 MACRecoverTime

The initial value of the macRecoverWhile timer.

23.6 State machine variables

23.6.1 BEGIN

This is a Boolean variable controlled by the system initialization process. A value of TRUE causes all TPMR state machines to continuously execute their initial state. A value of FALSE allows all state machines to perform transitions out of their initial state, in accordance with the relevant state machine definitions.

23.6.2 addConfirmed

Set by the other Port's SNM to tell STM that the addition has been confirmed. Cleared by STM.

23.6.3 disableMAC

Set by SNM to instruct the individual LAN MAC (via an LMI) to disable itself in a way that will cause MAC_Operational to be FALSE for the peer user of the MAC Service provided by that LAN.

NOTE—The state machines do not assume that a client of the MAC can tell whether the MAC is not operational because that client has disabled it, or whether some other client has disabled it.

23.6.4 disabledMAC

Set by the SNM when it has set disableMAC and for MACRecoverTime after disableMAC has been reset, so that the STM does not conclude that a loss notification should be sent through the other TPMR Port.

23.6.5 disableMSS

Set (or reset) by the STM to instruct the MSS (via an LMI) to set its MAC_Enabled status parameter to FALSE (correspondingly, TRUE).

23.6.6 lossConfirmed

Similar to addConfirmed but confirms a loss.

23.6.7 macOperational

The value of MAC_Operational for the individual LAN MAC.

23.6.8 mssOperational

The value of MAC_Operational provided by the MSS to the TPMR Port's Bridge transmit and receive function.

23.6.9 prop

Set by the other Port's STM to Add or Loss to notify SNM that a change is being propagated through the Port. Reset by SNM to None.

23.6.10 rxAck

Set by the Receive process to tell SNM that an acknowledgment has been received. Cleared by SNM.

23.6.11 rxAdd

Set by the Receive process to tell STM that an *add* notification is being propagated through the TPMR. Cleared by STM.

23.6.12 rxAddConfirm

Set by the Receive process to tell SNM that an *add confirm* has been received. Cleared by SNM.

23.6.13 rxLoss

Similar to rxAdd, but for a *loss*.

23.6.14 rxLossConfirm

Similar to rxAddConfirm, but for a *loss confirm*.

23.6.15 txAck

Set by the STM to instruct the Transmit process to send an acknowledgment. Cleared by the Transmit process.

23.6.16 txAdd

Set by the other Port's STM to cause transmission of an *add* notification. Cleared by the Transmit process.

23.6.17 txAddConfirm

Set by the other Port's SNM to cause transmission of an *add confirm* (through this Port) confirming that a received *add* message has been acted upon. Cleared by the Transmit process.

23.6.18 txLoss

Similar to a txAdd but causes a *loss* message to be transmitted.

23.6.19 txLossConfirm

Similar to a txAddConfirm but causes a *loss confirm* message to be transmitted.

23.7 State machine procedures

No procedures are defined beyond those represented in the state machines.

23.8 Status Transition state machine (STM)

The STM shall implement the function specified by the state diagram in Figure 23-10 and the attendant definitions contained in 23.4 through 23.7.

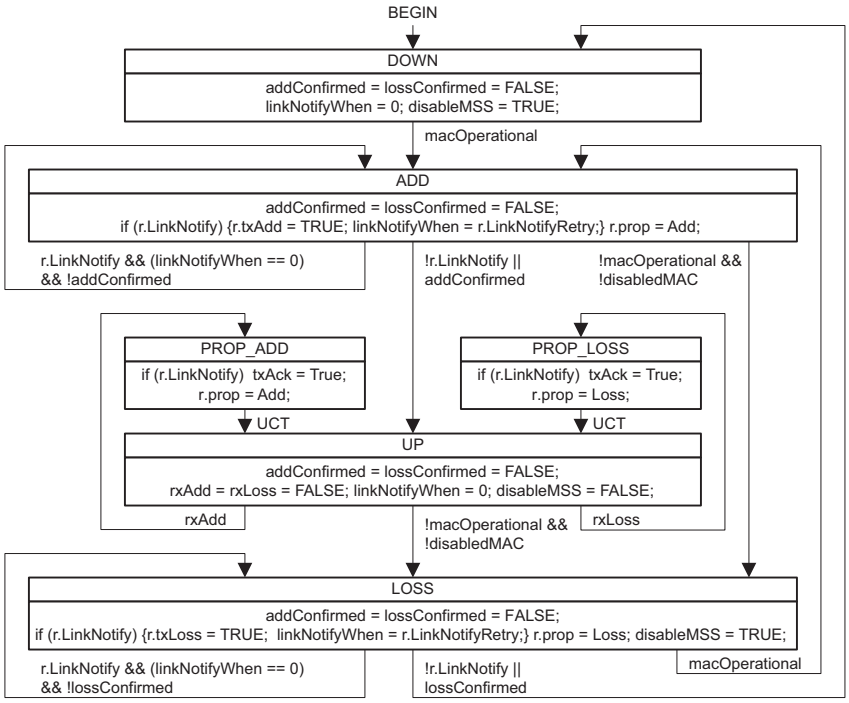

Figure 23-10—Status Transition state machine (STM)

23.9 Status Notification state machine (SNM)

The SNM shall implement the function specified by the state diagram in Figure 23-11 and the attendant definitions contained in 23.4 through 23.7.

23.10 Receive Process

The Receive Process shall receive and validate MSPDUs as specified in 23.16.

23.11 Transmit Process

The Transmit Process shall transmit and encode MSPDUs as specified in 23.13 through 23.15. If the Transmit Process is instructed to transmit an MSPDU before it has had the opportunity to transmit a prior MSPDU, that prior MSPDU shall be discarded and not transmitted. If the MAC_Operational status provided by the MSS for the Port is FALSE, the MSPDU shall be discarded and not transmitted.

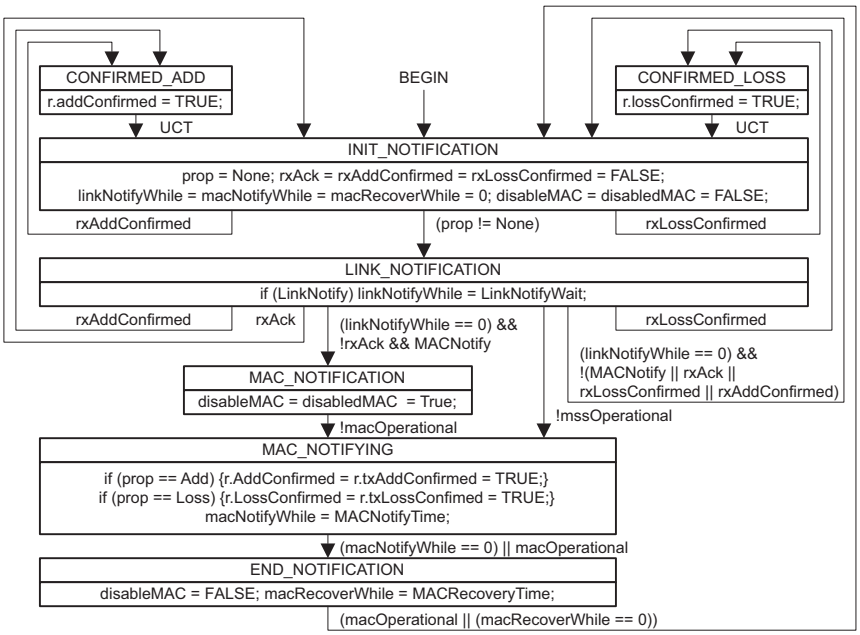

Figure 23-11—Status Notification state machine (SNM)

23.12 Management of MSP

An implementation of MSP in a TPMR:

a) May allow the performance parameters (23.5) to be read by management.
b) May allow the performance parameters (23.5) to be modified by management.
c) May maintain each of the following counts for one or both ports of the TPMR:
   1) acksTransmitted: The number of *acks* transmitted (23.6.15) by the Port's Transmit Process as a consequence of txAck being set.
   2) addNotificationsTransmitted: The number of *adds* transmitted (23.6.16) by the Port's Transmit Process as a consequence of txAdd being set.
   3) addConfirmationsTransmitted: The number of *add confirms* transmitted (23.6.17) by the Port's Transmit Process as a consequence of txAddConfirm being set.
   4) lossNotificationsTransmitted: The number of *loss*es transmitted (23.6.18) by the Port's Transmit Process as a consequence of txLoss being set.
   5) lossConfirmationsTransmitted: The number of *loss confirms* transmitted (23.6.19) by the Port's Transmit Process as a consequence of txLossConfirm being set.
   6) acksReceived: The number of *acks* received (23.6.10) by the Port's Transmit Process.
   7) addNotificationsReceived: The number of *adds* received (23.6.11) by the Port's Receive Process.
   8) addConfirmationsReceived: The number of *add confirms* received (23.6.12) by the Port's Receive Process.
   9) lossNotificationsReceived: The number of *loss*es received (23.6.13) by the Port's Receive Process.
   10) lossConfirmationsReceived: The number of *loss confirms* received (23.6.14) by the Port's Receive Process.
   11) addEvents: The number of transitions to STM:ADD directly from STM:DOWN or STM:LOSS (23.8).

12) lossEvents: The number of transitions to STM:LOSS directly from STM:UP or STM:ADD (23.8).
13) macStatusNotifications: The number of transitions to SNM:MAC_NOTIFICATION (23.9).

23.13 MSPDU transmission, addressing, and protocol identification

MSPDUs are transmitted and received using the service provided by an LLC entity that uses, in turn, a single instance of the MAC Service provided at an MSAP. In a TPMR the MSPE transmits and receives the MSPDUs, and the MSAP is provided by the TPMR Port connectivity function as illustrated in Figure 23-3. Each MSPDU is transmitted as a single MAC Service request, and received as a single MAC Service indication, with the following parameters:

a) destination address (23.13.1)
b) source address (23.13.2)
c) MSDU
d) priority (23.13.3)

The MSDU of each request and indication comprises an number of octets that provide EtherType protocol identification (23.13.4) followed by the MSPDU proper (23.15).

NOTE 1—For the purposes of this standard, the term “LLC entity” includes entities that support protocol discrimination using the EtherType field as specified in IEEE Std 802.

NOTE 2—The complete format of an MSP frame “on the wire” or “through the air” depends not only on the MSPDU format, as specified in this clause, but also on the media access method-dependent procedures used to support the MAC Service.

23.13.1 Destination MAC Address

The destination address for each MAC Service request used to transmit an MSPDU shall be the group address identified in Table 8-1 and Table 8-2 as “Nearest non-TPMR Bridge group address”[40].

23.13.2 Source MAC Address

The source address for each MAC Service request used to transmit an MSPDU shall be an individual address associated with the MSAP at which the request is made.

23.13.3 Priority

The priority associated with each MAC Service request should be the default associated with the MSAP. Transmitted MSPDUs are not VLAN tagged or priority tagged.

23.13.4 EtherType use and encoding

All MSPDUs are identified by the EtherType specified in Table 23-3.

Table 23-3—MSP EtherType assignment

Assignment	Value
MAC Status Protocol EtherType	22-E2

[40] This address was originally assigned by IEEE Std 802.1X-2001 and was identified as an S-VLAN component Reserved Address (Table 8-2) by the IEEE Std 802.1ad amendment to IEEE Std 802.1Q-2005. This standard identifies it as the “nearest non-TPMR Bridge group address,” to be filtered by all relay functions above the sublayer specified for TPMRs (see Table 8-1 and Table 8-2).

23.14 Representation and encoding of octets

All MSPDUs consist of an integral number of octets, numbered starting from 1 and increasing in the order that they are put into a MAC frame. The bits in each octet are numbered from 1 to 8, where 1 is the low-order bit. When consecutive octets are used to encode a binary number, the lower numbered octet contains the more significant bits of the binary number.

When the encoding of (an element of) an MSPDU is represented using a diagram in this clause, the following representations are used:

a) Octet 1 is shown toward the top of the page, higher numbered octets being toward the bottom.
b) Where more than one octet appears on a given line, octets are shown with the lowest numbered octet to the left, higher numbered octets being to the right.
c) Within an octet, bits are shown with bit 8 to the left and bit 1 to the right.

23.15 MSPDU structure

The MSPDU comprises the octets following the MSP EtherType. All MSPDUs comprise a Protocol Version (23.15.1) and a Packet Type (23.15.2). See Figure 23-12.

	Octet
Protocol Version (23.15.1)	1
Packet Type (23.15.2)	2

Figure 23-13—MSPDU structure

23.15.1 Protocol Version

The MSP Protocol Version is encoded in all MSPDUs as a single octet, representing an unsigned binary number. Its value identifies the version of MSP supported by originator of the MSPDU. An implementation conforming to this specification shall encode the value 0000 0000 in this field. All other values are reserved.

NOTE—TPMRs that relay an MSPDU do not change its Protocol Version.

23.15.2 Packet Type

The MSP Packet Type is encoded as a single octet, representing an unsigned binary number. Table 23-4 lists the Packet Types specified by this standard, and the state machine variables set to indicate reception and transmission of MSPDUs of that type. All other possible values of the Packet Type field are reserved and shall not be used.

Table 23-4—MSP Packet Types

Packet Type	Value	Transmission	Reception
MSP-Add	0	txAdd (23.6.16)	rxAdd (23.6.11)
MSP-Loss	1	txLoss (23.6.18)	rxLoss (23.6.13)
MSP-Add Confirmed	2	txAddConfirm (23.6.17)	rxAddConfirm (23.6.12)
MSP-Loss Confirmed	3	txLossConfirm (23.6.19)	rxLossConfirm (23.6.14)
MSP-Ack	4	txAck (23.6.15)	rxAck (23.6.10)

23.16 Validation of received MSPDUs

To ensure that backward compatibility is maintained for future versions of this protocol, the validation and protocol version handling for all MSPDUs, follows general rules developed for this and other protocols. A received MSPDU shall be processed as specified by Table 23-4 if and only if:

a) The destination MAC address is the group address specified (23.13.1); and
b) The MSPDU is identified by the MSP EtherType encoded as specified in 23.13.4; and
c) The received MSPDU contains at least two octets, i.e., at least the Protocol Version and Packet Type; and
d) The Packet Type is one of the values specified in Table 23-4.

Otherwise, the received MSPDU shall be discarded. No other checks shall be applied to received MSPDUs, in particular the value of the Protocol Version is not checked and MSPDUs of length greater than the minimum of two octets are accepted as valid.

23.17 Other MSP participants

An end station or non-TPMR Bridge attached to the end of a TPMR link can participate in link status notification, avoiding the need for the last TPMR in the chain to use MAC status notification and thus speeding the transition of the link to an operational state. Such a participant receives MSPDUs, but acts only on a received *loss* or *add*, notifying its protocol clients of the change in connectivity, and responding immediately by transmitting an *add confirm* or *loss confirm* as appropriate. There is no need for such a participant to transmit an *add*, *loss*, or *ack*, or act upon a received *ack*, *add confirm* or *loss confirm*, or to initiate MAC status notification.

24. Bridge performance

This clause specifies a set of parameters that represent the performance of a Bridge. These parameters have been selected to allow a basic level of confidence to be established in a Bridge, for use in an initial determination of its suitability for a given application. They cannot be considered to provide an exhaustive description of the performance of a Bridge. It is recommended that further performance information be provided and sought concerning the applicability of a Bridge implementation.

The following set of performance parameters is defined:

a) Guaranteed Port Filtering Rate, and a related time interval T_F , that together characterize the traffic for which filtering is guaranteed.
b) Guaranteed Bridge Relaying Rate, and a related time interval T_R.

24.1 Guaranteed Port Filtering Rate

For a specific Bridge Port, a valid Guaranteed Port Filtering Rate, in frames per second, is a value that, given any set of frames from the specific Bridge Port to be filtered during any T_F interval, the Forwarding Process shall filter all of the set as long as all of the following are true:

a) The number of frames in the set does not exceed the specific Bridge Port's Guaranteed Port Filtering Rate multiplied by T_F.
b) The Guaranteed Port Filtering Rate of each of the other Bridge Port(s) is not exceeded.
c) The Guaranteed Bridge Relaying Rate is not exceeded.
d) Relayed frames are not discarded due to output congestion (8.6.7).
e) The information upon which the filtering decisions are based has been configured in the FDB prior to the start of time interval T_F.

24.2 Guaranteed Bridge Relaying Rate

For a Bridge, a valid Guaranteed Bridge Relaying Rate, in frames per second, is a value that given any set of frames from the specific Bridge Port to be relayed during any T_R interval, the Forwarding Process shall relay all of the set as long as all of the following are true:

a) The number of frames in the set does not exceed the Bridge's Guaranteed Bridge Relaying Rate multiplied by T_R.
b) The Guaranteed Port Filtering Rate of each Bridge Port is not exceeded.
c) Relayed frames are not discarded due to output congestion (8.6.7).
d) The information upon which the forwarding decisions are based has been configured in the FDB prior to the start of time interval T_R.

24.3 RSTP performance requirements

This subclause places requirements on the performance of the Spanning Tree Protocol Entities of Bridges in a Bridged Network to ensure that RSTP operates correctly.

The delay between the occurrence of an external event and the action or actions mandated by the RSTP specification as a consequence of the event shall not exceed the Maximum RSTP processing delay specified in Table 24-1.

Table 24-1—Transmission and reception delays

Parameter	Absolute maximum value (s)
Maximum RSTP processing delay	1.0
Maximum BPDU transmission delay	0.2

External events subject to this provision of this specification shall include the following:

a) Transmission of a BPDU by another Bridge on a LAN to which the Bridge is attached.

Specified actions subject to this provision shall include the following:

b) Transmissions of BPDUs on all Ports mandated by the RSTP specification, with the exception of transmissions delayed by the Port Transmit state machine (13.34) to enforce transmit rate limits.
c) Ceasing to learn or forward frames.

The delay between internal timer related events and the transmission of all BPDUs on Ports mandated by the RSTP specification as a consequence shall not exceed the Maximum BPDU transmission delay specified in Table 24-1. Timer events subject to this provision of this specification shall include the following:

d) Decrementing of txCount by the Port Transmit machine, thus allowing a BPDU transmission if transmit rate limits were being enforced.
e) Expiry of the helloWhen timer (13.25.3).

25. Support of the MAC Service by PBBNs

A PBBN comprises a set of BEBs interconnected by some or all of the S-VLANs supported by a PBN (see Clause 16). Each BEB provides interfaces that encapsulate (or verify the encapsulation of) customer frames, thus allowing Customer MAC (C-MAC) addresses and VIDs to be independent of the Backbone MAC (B-MAC) addresses and VIDs administered by the PBBN operator and used to relay those frames across the backbone. The S-VLANs used to encapsulate customer frames are known as Backbone VLANs (B-VLANs), and the resources that support those VLANs are usually considered to be part of the PBBN.

NOTE 1—The term Customer used in the context of PBBs may refer to a first Provider who is purchasing service from a second Provider. The first Provider deploys a PBN or a PBBN within its domain. The second Provider deploys a PBBN within its domain. In this case, the first Provider is identified as a Customer with respect to the second Provider. The term Customer used here may alternatively refer to each of a pair of Providers communicating as peers.

Figure 25-1 shows peer BEBs within the MAC sublayer and their relationship to customer and backbone bridging functions. The right-most BEB shown is modeled as comprising two types of VLAN Bridge components, an I-component and a B-component, connected together. The two BEBs on the left of the figure each comprise a single VLAN Bridge component of different types. The left-most BEB has a single I-component, while the BEB just to the right of the left-most BEB has a B-component. A T-component may also be used in place of an I-component.

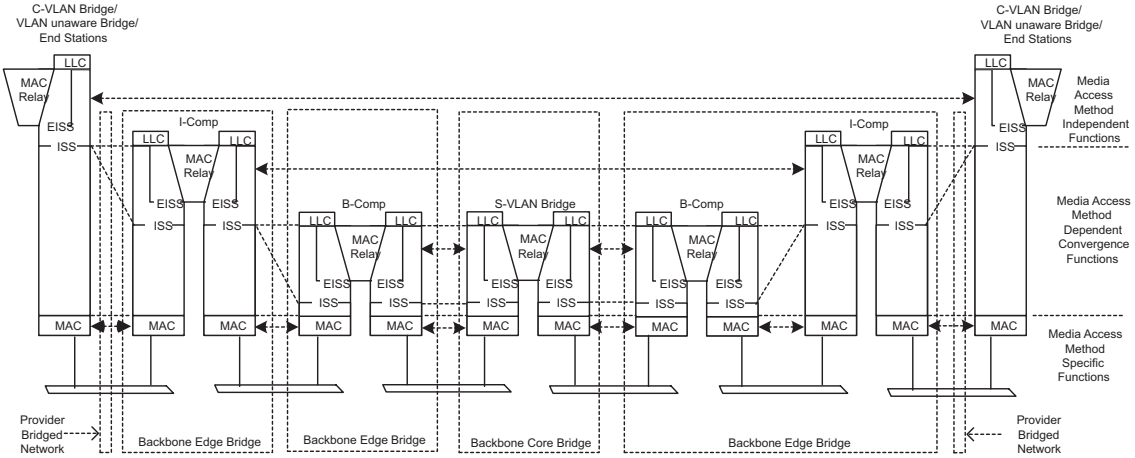

Figure 25-1—Internal organization of the MAC sublayer in a PBBN

Each I-component or T-component is responsible for encapsulating frames received from customers and assigning each frame to a backbone service instance. The backbone service instance consists of a set of BEBs that support a given customer's S-VLANs, and is uniquely identified within the PBBN by an I-SID. The customer frame is encapsulated by an I-TAG, which includes the I-SID, and a set of source and destination B-MAC addresses. The B-MAC addresses identify the BEBs of the backbone service instance where the customer frame will enter and exit the PBBN. If the I-component or T-component does not know which of the other BEBs provides connectivity to a given customer address, it uses a default encapsulating B-MAC address that reaches all the other BEBs in the backbone service instance. Each I-component learns the association between customer source addresses received (encapsulated) from the backbone and the backbone source address, so subsequent frames to that address can be transmitted to the correct BEB.

A PBBN or a series of PBBNs providing the MAC Service to attached end stations is typically modeled as a symmetric sequence of relay functions, as illustrated in Figure 25-1. The outermost peer relay functions are identified as I-components. The next peer relay functions in the sequence are identified as B-components.

Between the peer B-components are one or more S-VLAN relay functions. A B-component relay forms the service layer to an I-component relay. A B-component relay forwards frames taking into account the identity of a B-VLAN (B-VID), while an I-component relay forwards frames taking into account the identity of an S-VLAN (S-VID).

A single B-component is responsible for relaying encapsulated customer frames to and from I-components and T-components, either within the same BEB or externally connected, checking that ingress/egress is permitted for frames with that I-SID, translating the I-SID (if necessary) and using it to assign the supporting connection parameters (backbone addresses if necessary and VIDs) for the PBBN, and relaying the frame to and from the PNP(s) that provide connectivity to the other Bridges within and attached to the backbone. A B-component performs the same functions when relaying frames to and from another B-component when two PBBNs interconnect (26.6.2).

The number of I-components (zero or more), T-components (zero or more), and B-components (zero or one) within a given BEB is a direct consequence of the type and number of external interfaces supported by that BEB. The I-components, T-components, and B-component may be in the same BEB or may be in different BEBs. The types of BEBs may be classified as I-BEB, B-BEB, T-BEB, and ITB-BEB as depicted in Figure 25-2, where ITB-BEB covers all valid combinations of multi-component BEBs, e.g., IB-BEB.

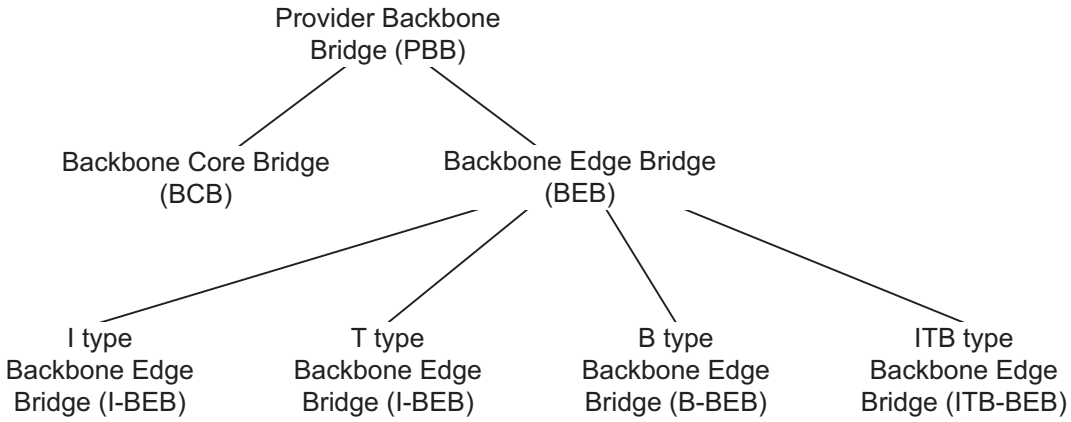

Figure 25-2—PBB terminology

This clause discusses the following aspects of PBBN service:

a) Service transparency (25.1)
b) Customer service interfaces (25.2, 25.3, 25.4, 25.5)
c) Service instance segregation (25.6)
d) Service instance and backbone service instance selection and identification (25.7)
e) Service priority and drop eligibility selection (25.8)
f) Service access protection (25.9)

NOTE 2—This standard makes use of the term *service* as defined by the OSI Reference Model (IS0/IEC 7498-1). In this sense, a service comprises a set of primitives and associated parameters, provided by one protocol layer in the architectural model to the protocol layer above, and the causal relationships between the primitives invoked by an upper layer protocol entity in one system with those resulting indications to a peer entity in another system. The term service used by backbone providers, while including layering concepts, goes far beyond this formal definition, and commonly specifies some or all of the following: interfacing considerations across multiple protocol layers (including physical connectors, for example); selection of interface points; interfacing equipment; QoS guarantees and measurement methods; charging methods and responsibilities; connectivity verification and other management tools; and regulatory issues.

25.1 Service transparency

The operation of PBBNs is, by design, largely transparent to Provider Bridges and PBNs as illustrated by Figure 25-1. The service provided by BEBs is transparent to the use of the MAC Service by end stations attached to the CBNs through PBNs and transparent to the operation of media access method-independent functions by Customer Bridges.

The service is not transparent to the operation of media access method-dependent convergence functions or to the operation of the media access method-specific functions specified by standards for each media access method. Media access method-dependent and -specific functions operate between Bridges—whether Customer Bridges, Provider Bridges, or PBBs—attached to the same LAN.

25.2 Customer service interface

A backbone provider can offer to customers one or more types of service interfaces, each providing different capabilities for service selection, priority selection, and service access protection (25.7, 25.8, 25.9). In some cases it is assumed the customer provides an S-VLAN component of a Provider Bridge while in other cases, more generic customer systems are also allowed. There are four basic types of customer service interfaces—Port-based, S-tagged, I-tagged, and transparent service interface. The customer service interface types are summarized by Figure 25-3.

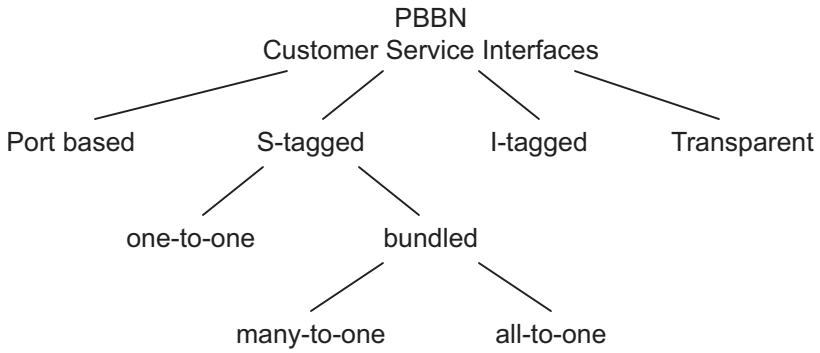

Figure 25-3—Customer service interface types

In all cases, segregation of different service instances is achieved at an interface wholly under the control of the backbone provider, and by verification of customer provided parameters that provide service instance selection. Stronger authentication and authorization of the attached customer systems can be achieved by use of IEEE Std 802.1X.

NOTE—The term service access protection describes provision of service access over multiple access LANs and (or) nodes with redundancy and rapid failover in case of failure of an access LAN or attached equipment.

Access to a given backbone service instance can be provided through different types of customer interfaces.

25.3 Port-based service interface

A PBBN may provide a Port-based service interface for customer attachment. The PBBN Port-based interface provides the same type of service to a customer as the PBN Port-based interface described in 15.3. A Port-based service interface is delivered on a CNP provided by a BEB as illustrated in Figure 25-4 and Figure 25-5. A Port-based service interface may attach to a C-VLAN Bridge (5.9), MAC Bridge, router, or end-station. The service provided by this interface forwards all frames without an S-TAG over the backbone on a single backbone service instance. All frames with an S-TAG that has a non-null VID are discarded by a Port-based service interface.

The Port-based service interface requires specific constraints on the configuration of the I-component. Each I-component CNP providing a Port-based interface is associated with one and only one VIP with exactly the same parameters for their tagging functions support. More specifically both CNP and VIP

a) Have the Acceptable Frame Types parameter configured to Admit Only Untagged and Priority-tagged frames.
b) Have equal PVID values.
c) Are exclusive members of the same PVID member set.
d) Are members of the PVID untagged egress set.

Figure 25-4 illustrates a customer system attached to a PBBN over a Port-based service interface.

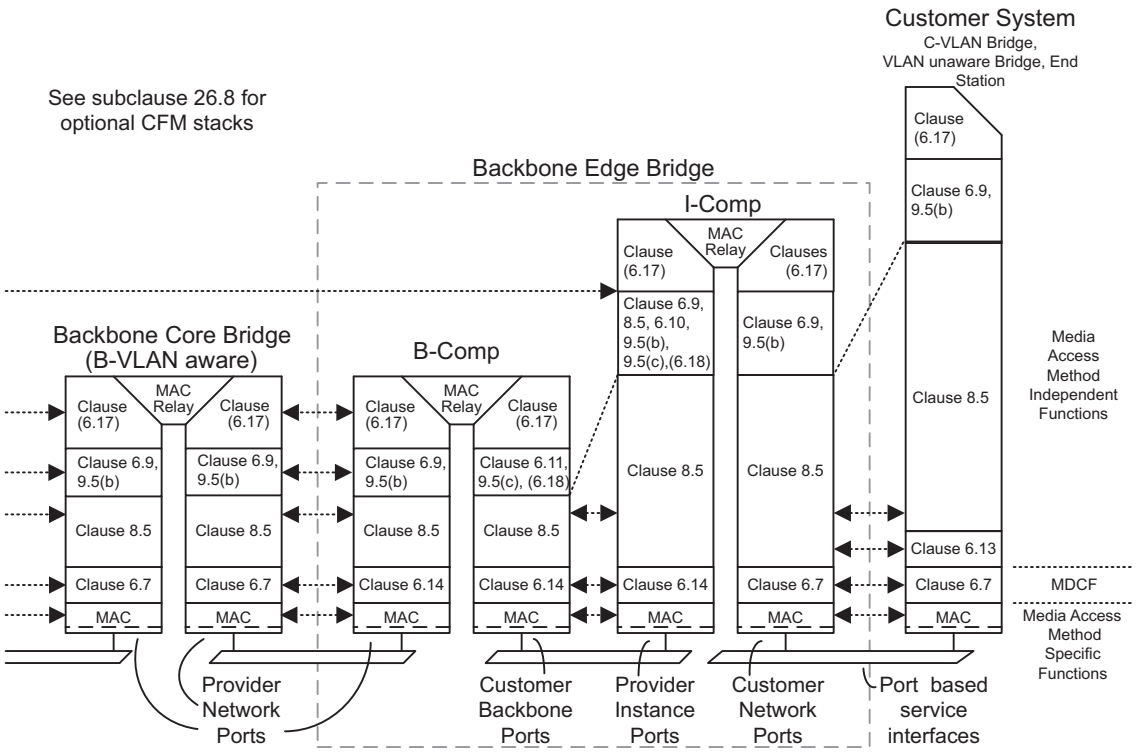

Figure 25-4—Port-based service interface

Figure 25-5 shows an example of equipment used to implement an unprotected Port-based service interface. For details on redundant connections and equipment, see 25.9. An I-component may support one or more Port-based service interfaces. Each CNP may be associated with one Port-based service interface. A CNP is connected to a customer system (or network) using a LAN.

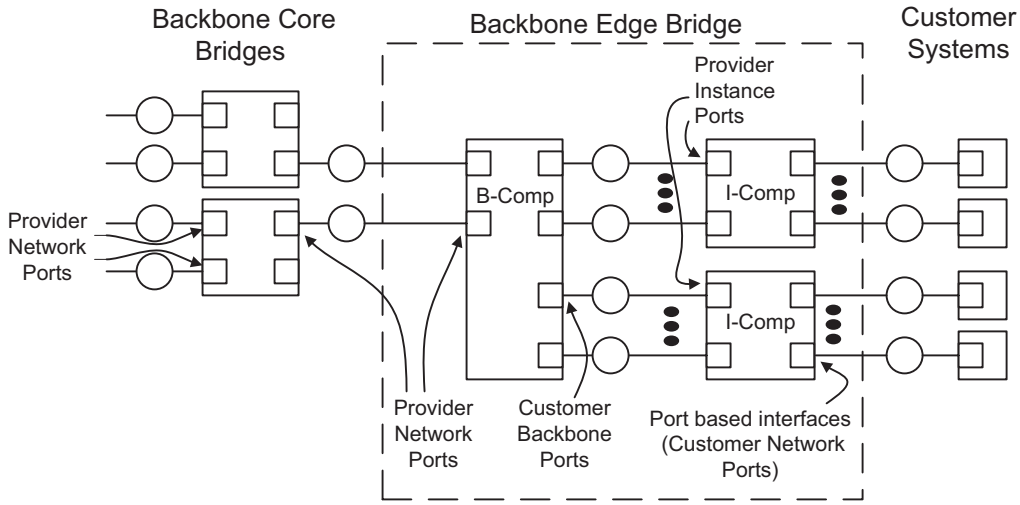

Figure 25-5—Port-based interface equipment

25.4 S-tagged service interface

The S-tagged service interface maps a service instance from a PBN, identified by an S-VID, to a backbone service instance on the PBBN, identified by an I-SID. There are two types of S-tagged service interfaces—one performing a one-to-one mapping of S-VIDs to I-SIDs and the other bundling S-VIDs to I-SIDs. Frames that are mapped to the I-SID are carried over the PBBN while frames that are not mapped to an I-SID are not carried over the PBBN.

NOTE 1—The restriction that each PBN S-VLAN map to a single backbone service instance on the PBBN allows the PBN equipment receiving frames to correctly identify the service instance used to deliver that frame and prevents the configuration of the I-component to create a multipoint service from point-to-point service instances, which could result in accidental creation of data loops. The backbone provider can offer a multipoint service through appropriate configuration of the B-VLAN component.

A PBBN may provide an S-tagged service interface for attachment to customer PBNs (15.5). An S-tagged service interface is provided by a BEB over a CNP as illustrated by Figure 25-7 and Figure 25-8. The attached Provider Bridges can in turn provide Port-based, C-tagged, or S-tagged service interfaces to their customers as described in 15.2, 15.3, 15.4, and 15.5.

The S-tagged service interface has the variations shown in Figure 25-3 under the S-tagged branch. The first variation, called a one-to-one S-tagged interface, uses a one-to-one mapping between S-VIDs and I-SIDs. This interface variation maps each S-VID to a single I-SID for use over the PBBN. The one-to-one mapped interface does not carry the S-TAG over the PBBN. The DEI and PCP bits may be regenerated on ingress and are then carried in the I-DEI and I-PCP bits in the I-TAG across the PBBN. On egress from the one-to-one S-tagged interface, the S-TAG can be deduced from the I-TAG received from the PBBN (the I-SID is mapped to an S-VID, the I-DEI and I-PCP bits may be regenerated and are then carried in the DEI and PCP bits).

The second S-tagged service interface variation is the bundling S-tagged service interface. This interface variation maps multiple S-VIDs to a single I-SID for delivery over the PBBN. To allow the remote end to reconstruct the S-VID, this interface variation will carry an S-TAG over the PBBN. On a bundled S-tagged interface, the DEI and PCP bits of the S-TAG may be regenerated and are then carried in both the DEI and PCP bits of the S-TAG and the I-DEI and I-PCP bits of the I-TAG over the PBBN.

A special case of the bundling S-tagged service interface is where all S-VIDs are mapped to a single I-SID. This special case is called an all-to-one bundling S-tagged service interface. The I-component used for an all-to-one bundled S-tagged service interface is constrained to supporting a single S-tagged service interface.

Figure 25-6 illustrates the information passed over each of the ISS interfaces of a BEB.

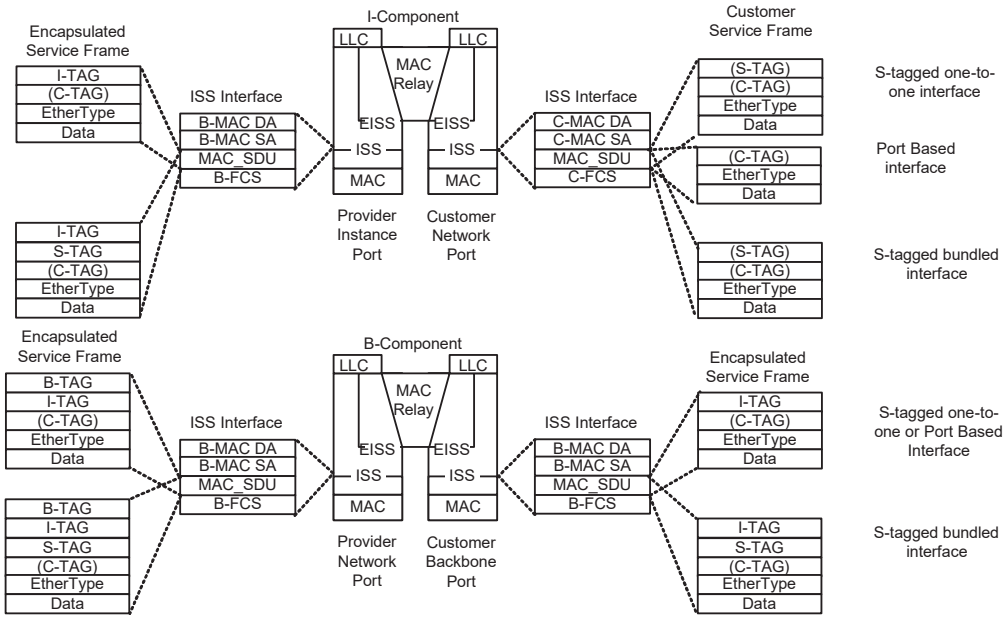

Figure 25-6—Encapsulated service frames at ISS

Figure 25-7 illustrates a customer network attached to a PBBN using an S-tagged service interface. The customer network uses Provider Bridges with S-VLAN components for connecting to the PBBN. The PBBN in turn is composed of BEBs interfacing to the customer Provider Bridges and BCBs used to forward frames between the BEBs.

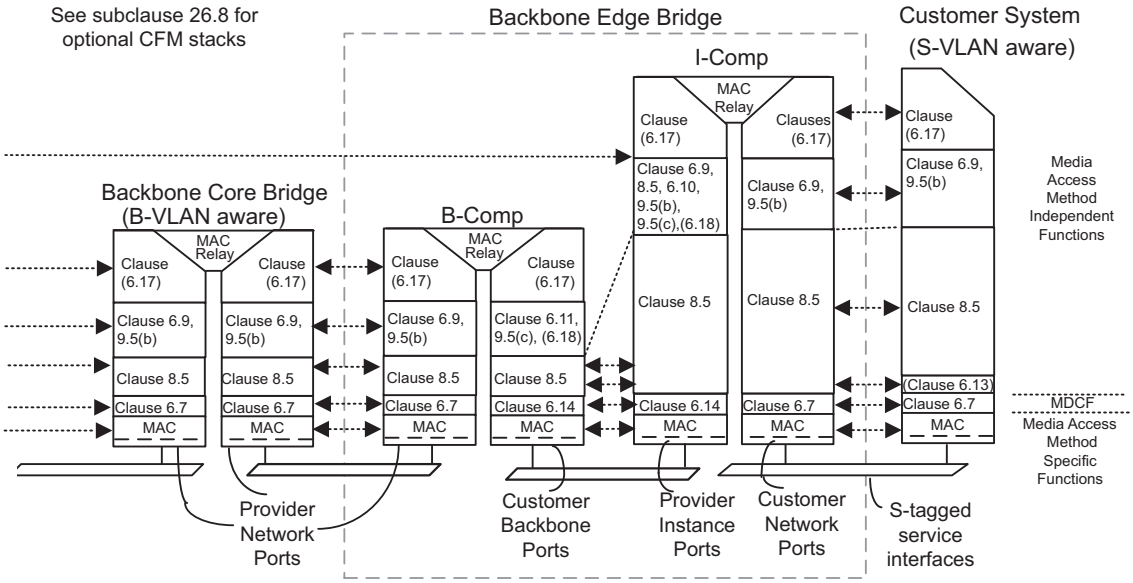

Figure 25-7—S-tagged service interface

Figure 25-8 shows an example of equipment used to implement an unprotected S-tagged service interface. For details on redundant connections and equipment, see 25.9. In this diagram, a BEB is formed by connecting two I-components and a B-component. These connections may be over a backplane or over a LAN. An I-component may support one or more S-tagged service interfaces. When an I-component supports an all-to-one bundled S-tagged service interface, the entire I-component must be dedicated to a single S-tagged service interface. Each CNP may be associated with one S-tagged service interface. A CNP is connected to a customer system (or network) using a LAN.

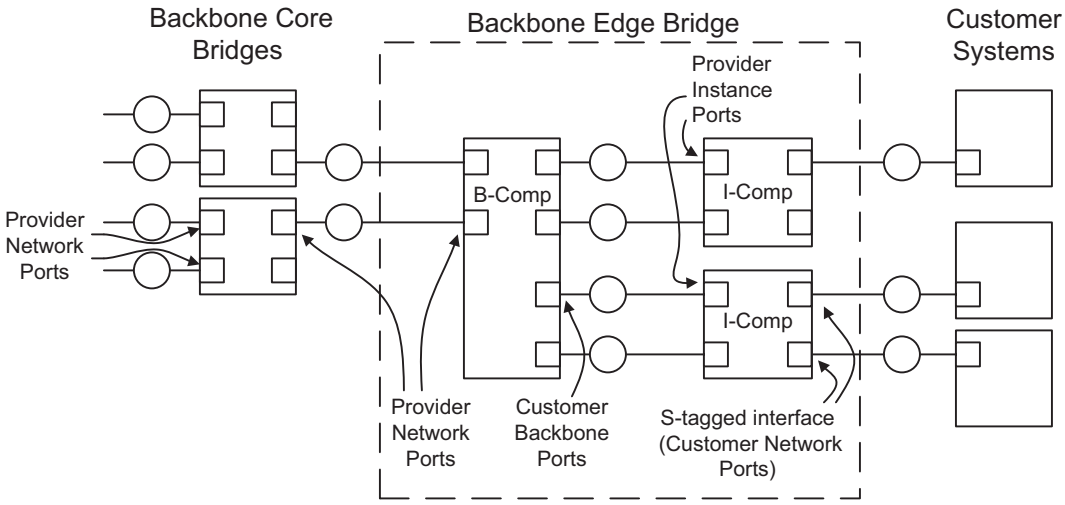

Figure 25-8—S-tagged service interface equipment

NOTE 2—It is always possible to build equipment that includes both BEB and Provider Edge Bridge components. In particular, it is possible for a BEB to support a C-tagged service interface (15.4) for attachment to a CBN by including a C-VLAN component with PEPs that connect to the CNPs of an I-component. A BEB can also support an RCSI (15.6) by including a C-VLAN component and a Port-mapping S-VLAN component.

25.5 I-tagged service interface

A PBBN may provide a native I-tagged service interface for attachment to another PBBN or for attachment to a customer's PIP. An I-tagged service interface can provide access to all the backbone service instances within a PBBN. Access to backbone service instances is controlled by the configuration of the CBP service instance tables (6.11). Each I-SID delivered over the I-tagged service interface by a customer identifies a service instance that will be carried over the PBBN. Service instances are carried over the PBBN inside a B-VLAN selected by the CBP. The customer must provide the B-DA for frames delivered to an I-tagged service interface.

Figure 25-9 illustrates a customer network attached to a PBBN using an I-tagged service interface. The customer network uses a BEB with an I-component (26.6.1) or a B-component (26.6.2) connecting to the PBBN. The PBBN in turn is composed of BEBs interfacing to the customer and BCBs in the core of the PBBN used to forward frames between the BEBs.

An I-tagged service interface may be provided at a CBP of a BEB as illustrated by Figure 25-9 and Figure 25-10. In this service interface, the I-SID provided over the service interface within the I-TAG is mapped 1-1 to an I-SID within the PBBN. As illustrated, a customer (or peer) may attach to the I-tagged service interface through a CBP. In this configuration, each PBBN is attached at a CBP.

Figure 25-10 shows an example of equipment used to implement an unprotected I-tagged service interface. For details on redundant connections and equipment, see 25.9. A B-component may support one or more I-tagged service interfaces. Each CBP may be associated with one I-tagged service interface. These CBP are connected to a customer system (or network) using an Ethernet LAN.

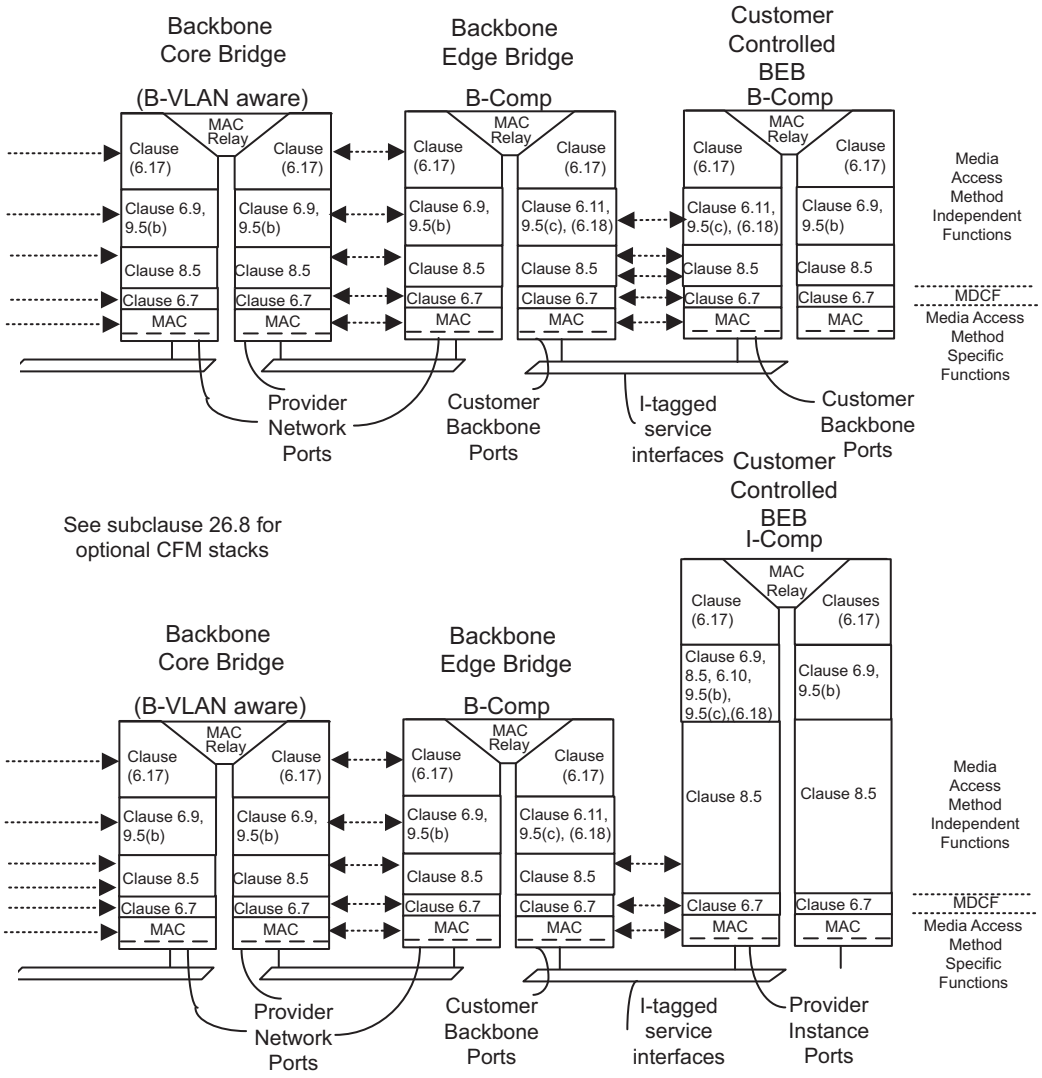

Figure 25-9—S-tagged service interface equipment

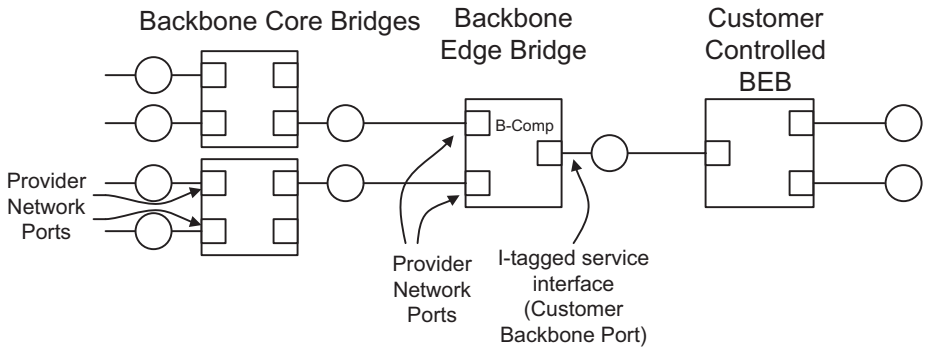

Figure 25-10—I-tagged service interface equipment

NOTE—A protected I-tagged service interface will have more than one PIP and can have a single backbone service instance, identified by an I-SID, enabled on more than one of those ports. This creates the potential for transit traffic on that backbone service instance to pass through the I-BEB without being delivered to a CNP. If this behavior is not desired, then the protected I-tagged service interface should be configured such that any single service instance is only enabled on a single PIP at any given time, or that only a single PIP is forwarding at any given time.

25.6 Service instance segregation

Segregation of data frames associated with different instances of MAC Service is achieved by supporting each service instance with a backbone service instance identified by an I-SID and ensuring that:

a) No service frames are transmitted through a CBP without an I-TAG.
b) No frames are accepted, i.e., received and relayed, from any customer system without first being subject to service instance selection.
c) No frames are delivered to any customer system without explicit service instance identification.
d) Prior to transmission through a PNP of a BEB, service frames are received either through an I-component's CNP or through a CBP. When the customer is attached to a CNP, the port is under the control of the backbone provider and is exclusively accessed by a single customer. In this case, the I-component used to support the CNP is under the control of the Backbone provider and is attached to a CBP through a PIP that is also under the control of the backbone provider and that may be shared with multiple customers. When the customer is attached to a CBP, the port is under the control of the provider and is exclusively accessed by a single customer. All frames received through the CNP or CBP (depending on how the customer is attached) must correspond to a service instance or instances that the customer is permitted to access. (The method used to ensure the port is attached to the specified customer and therefore secure is beyond the scope of this standard. See IEEE Std 802.1X.)
e) The BCBs and the B-component of each BEB within the PBBN can only be controlled by the provider.

A single backbone service instance may support many customer service instances. Each customer service instance is supported by a single backbone service instance.

25.7 Service instance selection and identification

Service instance selection is provided to the attached customer system by the Port-based, S-tagged, or I-tagged service interfaces (25.3, 25.4, 25.5). In the Port-based interface, only one backbone service instance is offered to the attached customer and the CNP of the I-component is configured to accept only untagged or priority tagged frames. In all S-tagged service interfaces, the CNP of the I-component is configured with Enable Ingress Filtering (8.6.2) and the Port is only included in the Member Set for S-VLANs corresponding to service instances that the customer is permitted to use. The service instance for each frame received by the attached customer system is identified in the same way as frames transmitted using the same interface, but not necessarily in the same way that the service instance is selected or identified at other interfaces. In the I-tagged service interface, the CBP of the B-component is configured (12.16.5, 6.11) with the acceptable backbone service instances and I-SID values for use by the customer. A single backbone service instance can support any combination of Port-based, S-tagged, or I-tagged service interfaces.

NOTE—The means used by a backbone provider and a customer to determine the S-VIDs and I-SIDs used by the customer to select and identify a given service instance are outside the scope of this standard.

25.8 Service priority and drop eligibility selection

For all service interface types, the service priority is selected using the received priority for each frame. For S-tagged and Port-based service interfaces, the priority and drop eligibility may be regenerated using the Priority Regeneration Table (6.9.4). For I-tagged service interfaces, the priority and drop eligibility may be regenerated using procedures of 6.11.

The mechanism for determining the received priority varies with the type of service interface. Service priority selection is provided for Port-based service interfaces using the received priority signaled from the media access method of the port. If the media access method used to attach to the interface does not directly

support priority, this will result in the selection of a single value for all frames. An attached system may also signal priority to a Port-based service interface on a per-frame basis by priority-tagging frames with an S-TAG that has a null VID (6.13).

Service priority selection is provided by S-tagged service interfaces using the PCP and DEI parameters conveyed in the S-TAG of each frame. An S-tagged service interface can provide a single backbone service instance for all S-VIDs received, and in this way functions like a Port-based service interface with the addition of the capability of delivering S-tagged service frames (whose S-TAG has a non-null VID).

Service priority selection is provided by I-tagged interfaces using the received priority decoded from the I-PCP and I-DEI fields in the I-TAG.

25.9 Service access protection

A customer system (or systems) that is part of a single PBN or that contains a customer operated I-component or B-component can attach to a PBBN using a protected service interface providing multiple LANs and (or) nodes, thus providing fault tolerance through redundancy of the service interface components. Three classes of service access protection may be supported (see Figure 25-11 and Figure 25-12), which provide for unprotected service interface, for link-level redundancy at the access link or link and node redundancy at the access point. An access service interface may be a Class I, II, III access service interface.

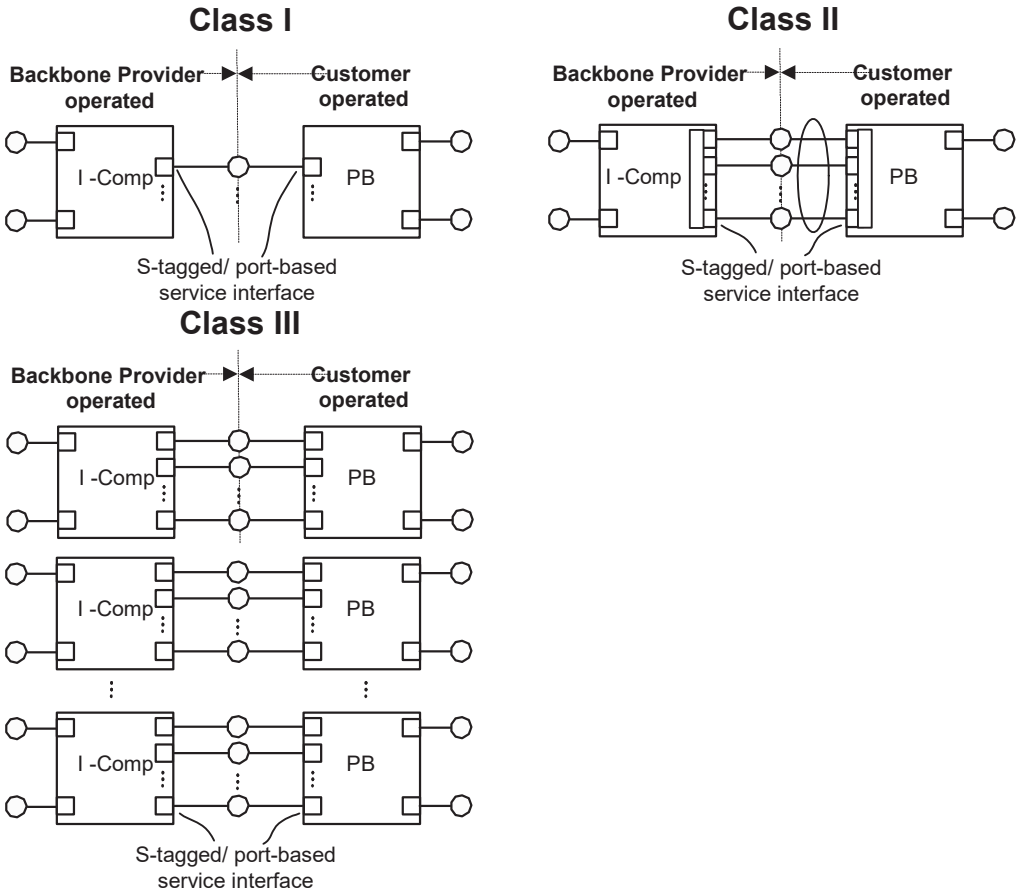

Figure 25-11—S-tagged and Port-based service interface access classifications

Protected Port-based, S-tagged, and I-tagged service interfaces are depicted in Figure 25-11 and Figure 25-12, respectively.

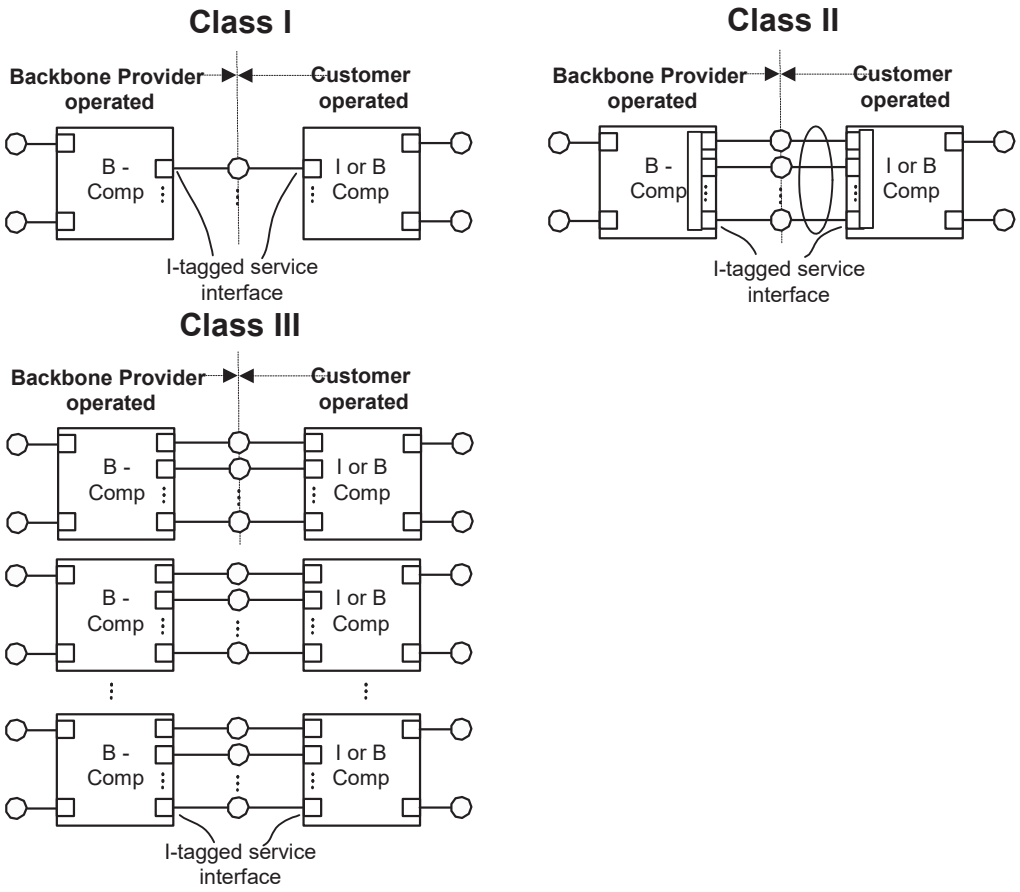

Figure 25-12—I-tagged service interface access protection classifications

Class I service interfaces depicted in these figures are unprotected service interfaces providing a single LAN and node. Class I service interface equipment is depicted in Figure 25-5, Figure 25-8, and Figure 25-10. These provide no redundancy and therefore will fail if any LAN or component fails.

Class II service interfaces are link protected service interfaces that provide multiple LANs; however, they do not provide any node redundancy. Class II service interfaces are tolerant of single or multiple LAN failures. These provide no node redundancy and therefore will fail if any node fails.

Class III service interfaces are link and node protected service interfaces providing multiple LANs and multiple nodes. Class III service interfaces are tolerant of single or multiple LAN failures and/or single or multiple node failures. The operation of a Class III service interface switches between access nodes within both the customer and provider networks; therefore, protection switching over a Class III service interface always results in state changes spreading over the customer and provider networks.

To attach a PBN to a PBBN, the following rules must be maintained to ensure loop-free operation over the extended network:

a) Each PBN and PBBN prevents forwarding loops by running an independent spanning tree.
b) Each PBN connects to other PBNs only through a PBBN.

c) Each PBN ensures that no data frame passes through more than one BEB attachment point into or out of the PBBN. An attachment point is a single LAN connection to a PBBN. This connection may be part of a protected or unprotected Port-based (see Figure 25-4), S-tagged (see Figure 25-7), or I-tagged service interface (see Figure 25-9). A PBN may use L2GP (13.40) to ensure only a single link is active when using a backup link to the PBBN.

d) Each PBN ensures that it attaches any given S-VLAN to no more than one PBBN.

NOTE—When an attached PBN uses the L2GP (13.40) to enforce criterion c), then the PBBN may implement a Class I, II, or III protection interface. If the PBBN is configured for Class I or II protection, then it will provide multipoint services with the services delivered to two or more Class I or II interfaces for attachment to the PBN. In this case, the PBN is responsible for selecting one of the two attachments using the L2GP to ensure criterion c). If the PBBN is configured for Class III protection, then the PBN must support MVRP over the access links to inform the PBBN which S-VIDs are active on which LAN connections.

25.9.1 Class II redundant LANs access protection

A Class II redundant interface is implemented using IEEE Std 802.1AX (Link Aggregation). Using Link Aggregation, a single CNP and associated PNP of a Provider Bridge, or CBP and associated PIP, may be implemented using multiple LANs. A failure on any of the LANs implementing the link will cause all traffic to migrate to the remaining LAN. CFM may run both on the aggregate and on each individual link as shown in Figure 22-8.

It is desirable for the distribution algorithm used on a Class II interface to divide traffic between the multiple links based on the service instance. One distribution algorithm that always retains a service on a single LAN is to place all the traffic on one of N links. In the event of a failure, all traffic is shifted to the highest priority remaining link. This distribution algorithm has the advantage that it provides for full reserved bandwidth on the backup link.

Another distribution algorithm that divides traffic by service and also allows traffic on all redundant links is to divide the traffic by either the S-VID or the I-SID. Distributing traffic based on the S-VID would be used for traffic over multiple LANs comprising an S-tagged interface, while distributing traffic based on the I-SID would be used for traffic over multiple LANs comprising an I-tagged interface. With either of these distribution schemes, services are allocated to one of the LANs used to implement the provider CNP or CBP and the customer PNP, PIP, or CBP. In the event of a failure, the services are moved to the remaining LANs.

25.9.2 Class III simple redundant LANs and nodes access protection

A Class III interface uses redundant LANs to connect a primary and one or more secondary customer nodes to a primary and one or more secondary BEBs. The operation protects the interface against failures on any of the interconnecting LANs or nodes used on each side of the interface. It is possible to use Class II protected interfaces for each link of the Class III interface. In this case, the Class II protection procedures must happen first and complete before a Class III protection switch begins.

For a Class III interface, each customer node is connected to a BEB using a single LAN. The interface is provisioned with a priority for each LAN that is part of the interface. Each of the LANs is constantly monitored using either PHY management, CFM, or both. In operation, a Class III interface uses only the highest priority operating LAN for traffic. The other LANs are protection paths. In a Class III interface, any switch in the LAN used for traffic will also switch both the customer node and the PBBN BEB since the connections of a Class III interface are sets composed of a customer node, a LAN, and a BEB.

When providing a Class III protected S-tagged interface, multiple CNPs, each on a different BEB, are used to create a single S-tagged interface. Each LAN of the S-tagged interface executes CFM at the port level to detect failures over the interface LANs. Information from CFM is used by the customer to determine which LANs of the S-tagged interface are operating and which are inactive. Each customer network runs MSTP to determine which S-VLANs are active on which LANs of the Class III interface. To avoid loops through the

Class III interface, either the I-components participate in the customer network spanning tree (13.42), or the ports on the customer equipment that connects to the I-components are configured as Layer 2 Gateway Ports (13.40). Upon an active link failure between customer node and its corresponding BEB or upon the customer node failure, the customer network switches to one (or more) of the backup links and informs the PBBN which S-VLANs are active on which links using MVRP (11.2) on the access LANs. The BEB(s), upon receiving the MVRP message(s) from the customer network, generate the corresponding MRP-based message(s) for the affected I-SIDs and send these messages over the associated B-VLANs. The far-end BEBs, upon receiving these messages, will flush their C-MAC entries in their FDB corresponding to the affected I-SIDs.

When providing a Class III protected I-tagged interface, multiple CBPs, each on a different B-BEB, are used to create the single I-tagged interface. In this scenario, each B-BEB is connected via a single link to the customer I-BEB where the link can be Class II protected. The customer I-BEB is in turn connected via multiple CNPs to the customer network. Each customer network runs MSTP to determine which S-VLANs are active on which LANs of the Class III interface. To avoid loops through the Class III interface, either the I-components participate in the customer network spanning tree (13.42), or the ports on the customer equipment that connects to the I-components are configured as Layer 2 Gateway Ports (13.40). PHY management or port-level CFM is used to detect failures over the interface LANs between the customer I-BEBs and the customer network. When a failure is detected, the customer network informs the customer I-BEBs which S-VLANs are active on which links using MVRP (11.2). The customer I-BEBs in turn notify the provider B-BEBs using MRP-based messages corresponding to the effected I-SIDs. The provider B-BEBs relay this message to the other BEBs in the PBBN over the associated B-VLANs. The far-end BEBs, upon receiving these messages, will flush their C-MAC entries in their FDB corresponding to the effected I-SIDs. Each LAN of the I-tagged interface also executes PHY management or CFM at the port level to detect failures over the I-tagged interface. In case of a complete I-tagged interface failure between the customer I-BEB and the provider B-BEB, the I-BEB uses this info to deactivate all its CNP ports toward the customer network.

25.10 Support of the MAC Service by a PBB-TE Region

A PBB-TE Region comprises a continuous set of IB-BEBs and BCBs, capable of providing TESIs, that have allocated a common subset of B-VIDs to the control of an external agent (8.9) responsible for setting up Ethernet Switched Paths (ESPs). Each IB-BEB that belongs to a PBB-TE Region can provide interfaces that encapsulate customer frames in ESPs, thus allowing the PBBN operator to offer TESIs.

A PBB-TE Region providing the MAC Service to attached stations is modeled as a sequence of relay functions, as illustrated in Figure 25-1. The MST Configuration Table associated with each BCB or B-component of an IB-BEB specifies a set of VIDs, each of which may be exclusively used throughout the PBB-TE Region to form part of an ESP identifier. Such a VID is called an ESP-VID and is associated with a special value of the MSTID in the MST Configuration Table, the TE-MSTID (8.9), indicating that the VID is not under the control of a spanning tree protocol.

The I-components of IB-BEBs supporting PBB-TE are responsible for encapsulating frames received from customers and allocating each frame to a backbone service instance and for decapsulating frames received from the network via backbone service instances. The allocation of customer frames to backbone service instances that will be transported by TESIs is done at the PIP as described in 6.10. At the PIP the customer frame is encapsulated by an I-TAG, which includes the I-SID, and a set of source and destination B-MAC addresses. The source B-MAC address is the PIP MAC address that is configured to take the same value as the CBP MAC address of the internally connected CBP on the B-component. As a result, the B-MAC addresses of frames associated with TESIs, the ESP MAC addresses, are always equal to the CBP MAC addresses.

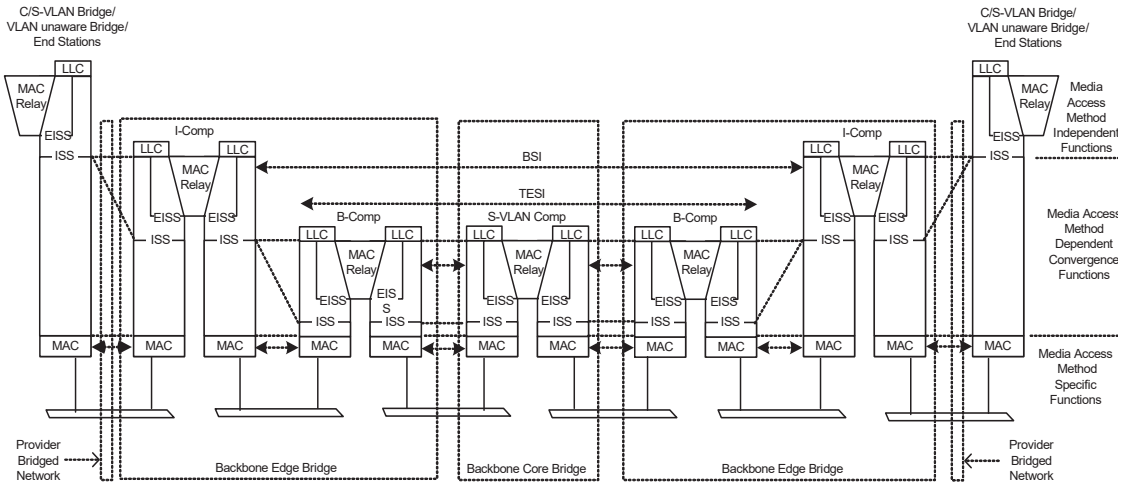

Figure 25-13—Internal organization of the MAC sublayer in a PBB-TE Region

CBPs on B-components in IB-BEBs supporting PBB-TE use the I-SID to map the encapsulated customer frames to TESIs or B-VLANs (6.11). Figure 25-1 depicts a TESI providing the MAC Service at two CBPs. For an I-SID mapped to a TESI, the Backbone Service Instance table contains the terminating CBP's MAC address, the ESP-DA, and the ESP-VID of the associated ESP. I-SIDs mapped to a B-VLAN must not use a B-VID from the ESP-VID space. The B-Component MAC relay forwards frames belonging to an ESP between the CBP and PNPs or between PNPs using the ESP-DA and ESP-VID as described in 8.6.

25.10.1 Provisioning TESIs

ESPs are provisioned in a PBB-TE Region by an external agent. This replaces the spanning tree protocols and populates the filtering tables of the corresponding B-components and BCBs by creating static filtering table entries for the ESP MAC addresses and ESP-VIDs (Figure 25-14).

The ability of a PBB-TE Region to utilize an external management or control plane is facilitated by PBB because the PIP MACs and correspondingly the ESP MAC addresses can be managed by the Provider and therefore can all be identified in the Provider's topology by the external management or control plane.

The external PBB-TE management/control plane is responsible for maintaining and controlling all the active topology information to support point-to-point or point-to-multipoint ESPs over the PBB-TE Region. The PBB-TE active topology can co-exist with active topologies associated with spanning tree protocols and the allocation to a specific active topology is governed by the B-VID value. The PBB-TE external agent takes control of the ESP-VID range on the Bridges in a PBB-TE Region.

Similar to the forwarding connectivity created by the operation of spanning tree and learning, the PBB-TE management/control plane can form an active topology of CBP rooted trees, from each CBP belonging to a PBB-TE Region to a specific subset of any other CBPs in this region. These traffic engineered trees define the path(s) taken by the frames that belong to ESPs within the PBB-TE Region. Furthermore each such tree is further qualified by the PBB-TE reserved ESP-VID, thus enabling the construction of independent trees per ESP-VID. As a result each such CBP rooted tree can be identified by a CBP MAC address associated with the root of the tree, the CBP MACs associated with the leaves of the tree and the ESP-VID. The PBB-TE management/control plane routes the ESPs along these trees by explicitly populating the FDBs in the Bridges along each tree with the Static Filtering Entries containing the CBP MAC DA and ESP-VIDs. The mechanism by which the PBB-TE management/control plane selects the path for a routing tree is not within

the scope of this standard. The PBB-TE management/control plane also manages the bandwidth of all ESPs along each routing tree. For each destination CBP, which is part of a routing tree maintained by the PBB-TE management/control plane, PBB-TE will maintain tree(s) which provide symmetric paths from the CBP MAC DA to the CBP MAC SA. The ESP-VID(s) used in this reverse ESP(s) need not have the same ESP-VID used for the forward ESP. Accordingly each of the ESPs can be identified by a 3-tuple:

<ESP-DA, ESP-SA, ESP-VID>,

where the three component fields are described as follows:

a) The ESP-SA is the address of the PIP encapsulating the customer service instance that by configuration is the same as the address of the internally connected source CBP.
b) The ESP-DA is identifying the CBP destination address(es).
c) The ESP-VID is a VID value distinguishing among ESPs having the same <destination, origin> pair. It can only take values that are allocated to the PBB-TE Region identified by the TE-MSTID (8.9).

An ESP is point-to-point or point-to-multipoint.

d) A point-to-point ESP is an ESP where the ESP-DA and the ESP-SA in its 3-tuple identifier are individual MAC addresses.
e) A point-to-multipoint ESP is an ESP between one root CBP to *n* leaf CBPs, identified by a 3-tuple where the ESP-DA is a group MAC address identifying the *n* leaves CBPs, and the ESP-SA is the individual MAC address of the root.

A TESI, is an instance of the MAC Service supported by a set of ESPs, collectively identified by a single TE-SID, forming a bidirectional service. The following two types of TESIs are described:

f) A point-to-point TESI that is supported by two point-to-point ESPs where the ESPs' endpoints have the same CBP MAC addresses.
g) A point-to-multipoint TESI that is supported by a set of ESPs that constitute one point-to-multipoint ESP from a root to each of *n* leaves plus a point-to-point ESP from each of the *n* leaves to the root.

NOTE—For reasons relating to TESI monitoring diagnostics, operational simplicity, etc., this standard assumes the point-to-point ESPs associated with a point-to-point TESI are symmetric and that the point-to-point ESPs associated with a point-to-multipoint TESI are routed from each of the *n* leaves to the root along the branches of the point-to-multipoint ESP. Support for a TESI that comprises ESPs not routed in this way is problematic, and is not defined in this standard.

Although an ESP is identified by the 3-tuple <ESP-DA, ESP-SA, ESP-VID> it is only the ESP-DA, ESP-VID pair that are used for forwarding decisions. The combination (ESP-DA, ESP-VID) is treated as though it was a single 60-bit address, where 12 bits are the ESP-VID and 48 bits are the ESP-DA. This ESP-VID field is used as a path selector to the destination CBP rather than a B-VID, allowing up to 2^{12} unique routing trees to any single CBP. In Figure 25-14, two paths are configured to reach S2. These two paths are separated by using a different ESP-VID in combination with the ESP-DA for a second path.

If the ESP-VID range delegated is the 4094 possible values, then each CBP termination can sink ($2^{12} – 2$) routing trees, and the theoretical network maximum is about 2^{60} ESPs. The number of ESPs supported by PBB-TE is constrained by issues related to coordinated management, independent management of groups of nodes or independent routing choices through parts of the path, limit through intermediate nodes, etc. In the cases where B-VLAN services are also offered by the same network, it is expected that most B-VIDs will be allocated to those B-VLANs since the use of the MAC addresses as part of the ESP identifiers allows at least 2^{48} ESPs and the ESP-VIDs can be used mainly to provide path diversity.

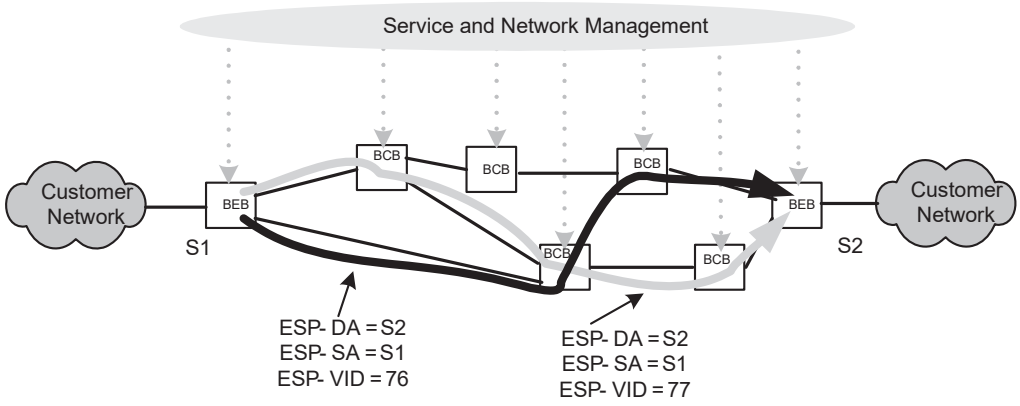

Figure 25-14—PBB-TE Region

25.10.2 ESP forwarding behavior

Forwarding of frames belonging to an ESP-VID differs from forwarding of frames belonging to B-VLANs in the following ways:

a) Frames associated with the ESP-VID are discarded when a Static Filtering Entry corresponding to the (ESP-DA, ESP-VID) is not found in the FDB [item b) in 5.4.5]. Proper operation of PBB-TE requires the provisioning of an FDB entry in each Bridge through which an ESP passes in order to specify the forwarding of traffic associated with that ESP. Such an entry may be absent due to a provisioning error. In the event of such an error, it is important that frames associated with the improperly configured ESP not be flooded, as PBB-TE would be violated if traffic intended for a particular ESP is sent on one or more other ESPs. Further, flooding based on the ESP-VID may result in unbounded looping and replication as the ESP-VID is not associated with a spanning tree. For this reason, frames associated with the ESP-VID are discarded when a Static Filtering Entry corresponding to the (ESP-DA, ESP-VID) is not found in the FDB. Such an ESP MAC address may represent an individual address, for which no more specific Static Filtering Entry exists or a group address, for which no more specific Static Filtering Entry exists (8.8.1).

b) MAC learning is not performed on receipt of a frame carrying an ESP-VID [item a) in 5.4.5]. Where ESPs have been correctly provisioned, learning would not interfere with the proper operation of Bridges, but in the presence of provisioning errors, learning may result in undesired behavior.

c) The active topology for the ESP-VIDs allocated to PBB-TE is no longer controlled by spanning tree protocols but by an external agent that is responsible for setting up the ESPs [item b) in 5.4.5].

NOTE 1—In a network supporting both VLAN (i.e., PBB) and ESP (PBB-TE) traffic, the establishment of an ESP and the policing of traffic at the ingress of the ESP are necessary but not sufficient conditions to ensure that traffic associated with an ESP receives the QoS intended by the network operator. The operator should ensure that the QoS requirements of an ESP are satisfied and that sufficient network capacity is available to accommodate broadcast-unknown traffic, spanning tree control traffic, and other traffic associated with VLAN usage.

Key properties of an ESP are as follows:

d) The ESP is identified at all points along its path by a single identifier <ESP-DA, ESP-SA, ESP-VID>.

e) The information referenced for forwarding <ESP-DA, ESP-VID> is contained within the ESP Identifier.

f) The information referenced for forwarding <ESP-DA, ESP-VID> does not change along the length of the ESP.

NOTE 2—The static and provisioned nature of an ESP provides support for traffic engineering. These properties of the ESP, together with policing and queuing functions supported by a Bridge (8.6) can provide per ESP QoS.

25.11 Transparent service interface

A PBBN may provide a transparent service interface for customer attachment. A transparent service interface is delivered on a CNP provided by a BEB as illustrated in Figure 25-15 and Figure 25-16. A transparent service interface may attach to a Provider Bridge, C-VLAN Bridge (5.9), MAC Bridge, router, or end-station. The service provided by this interface forwards all frames over the backbone on a single backbone service instance.

A transparent service interface does not recognize, add, remove, or modify either S-tags or C-tags on customer frames. It does not learn customer addresses, nor does it filter frames based on any MAC addresses except the TPMR component Reserved addresses listed in Table 8-3 and the management address of the TPMR component.

Figure 25-15 illustrates a customer network attached to a PBBN using a transparent service interface. The customer network uses End Stations, Customer Bridges, or Provider Bridges for connecting to the PBBN.

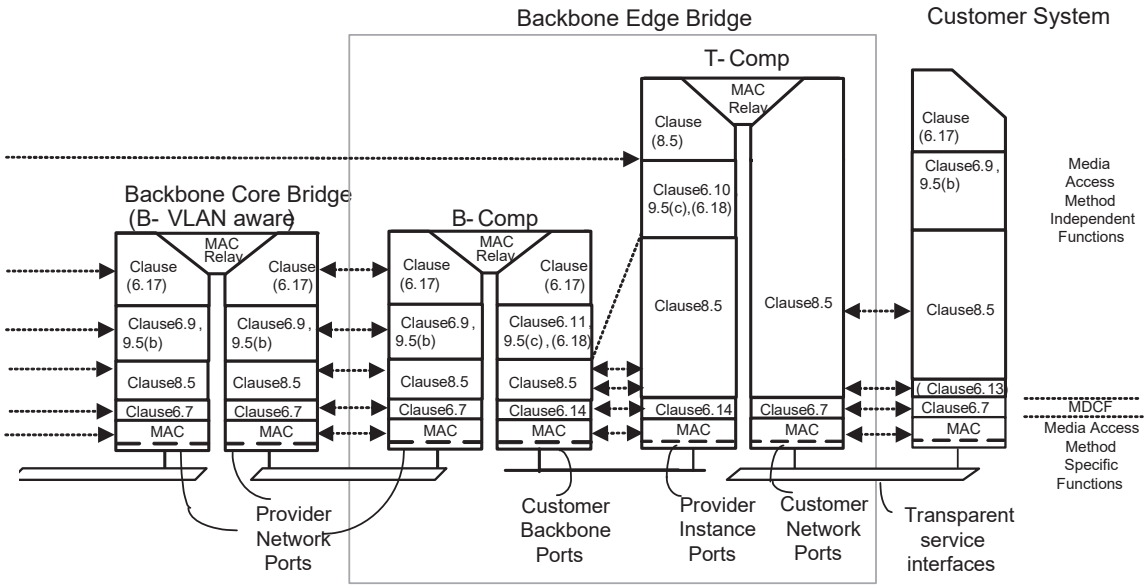

Figure 25-15—Transparent service interface

Figure 25-16 shows an example of equipment used to implement a transparent service interface. In this diagram a BEB is formed by connecting two T-components and a B-component. These connections may be over a backplane or over a LAN. A T-component supports a single transparent service interface associated with a CNP. A CNP is connected to a customer system (or network) using a LAN.

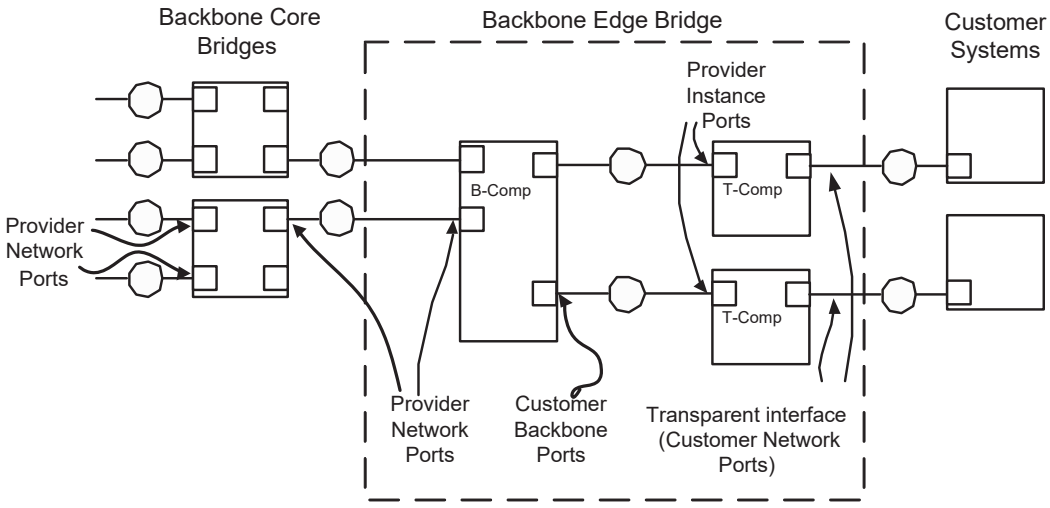

Figure 25-16—Transparent service interface equipment

26. Principles of Provider Backbone Bridged Network (PBBN) operation

This clause establishes the principles and a model of PBBN operation. It provides the context necessary to understand how the:

a) Operation of individual Backbone Edge Bridges (BEBs) and Backbone Core Bridges (BCBs) (Clause 8, Clause 25);
b) Configuration and management of individual BEBs and BCBs (Clause 12); and
c) Management of spanning tree and VLAN topologies within a PBBN (Clause 7, Clause 11, and Clause 13)

support, preserve, and maintain the quality of each of the instances of the MAC Service offered to the customers of the PBBN (Clause 6, Clause 25) including the following:

d) Independence of each service instance supported by a PBBN from other service instances (25.6).
e) Identification of service instances and backbone service instance within the PBBN (25.7, 8.8).
f) Maintenance of service availability in the event of the failure, restoration, removal, or insertion of LAN components connecting a customer network to a PBBN (Clause 6, Clause 11, Clause 13, 25.9).

A PBBN is a Virtual Bridged Network that comprises BEBs at the edge of the PBBN and BCBs at the core of the PBBN and attached LANs, under the administrative control of a single backbone provider. The principal elements of PBBN operation are those specified in Clause 16, as amended by this clause.

NOTE 1—The term PBBN is used exclusively to refer to networks configured and managed as specified by this clause and comprising only (a) BCBs and BEBs and (b) communications media and equipment providing the ISS (IEEE Std 802.1AC). While the requirements of Clause 25 are generally applicable to similar services, a generalized framework for all the network designs that could support these requirements, while useful in the context of other equipment and services, is outside the scope of this standard. This clause describes specific best practice for PBBNs to ensure that the requirements for Bridge functionality are clear. Conformance of a BEB implementation to this standard does not require that the implementation be used as specified in this clause; merely, that it is capable of being so used.

NOTE 2—Within a PBBN, an instance or instances of the MAC Service are reserved for the backbone provider's own use to configure and manage the network. All frames associated with such service instances, and that are not confined to an individual LAN, are subject to service instance selection, segregation, and identification as specified in 26.1.

26.1 PBBN overview

The principal elements of PBBN operation comprise the following:

a) Encapsulation/de-encapsulation of service frames in B-MAC Frames (6.10).
b) Service instance segregation within a PBBN for service frames (25.6).
c) Service instance selection on ingress, and service instance identification on egress, for each customer frame (25.7).
d) Service access protection (25.9).
e) Resource allocation and configuration to provide service instance connectivity (26.3).

The following may also be included:

f) Management of customer end station address learning (26.4)
g) Prevention of connectivity loops formed through attached networks (26.5)
h) Scaling of PBBNs (26.6)
i) Provisioning of PBBN services (26.7)
j) Management of PBBN service connectivity (26.8)

26.2 PBBN example

An example PBBN is illustrated by the Figure 26-1. The example network is divided into three major areas: the customer equipment area, which is owned by the customer and is interfaced to the PBBN; the PBBN area, which is owned by the backbone provider and interconnects to the customer equipment and to other PBBNs; and the other PBBN area, which is owned by the same or other backbone providers and interconnects to multiple PBNs allowing the network to scale indefinitely.

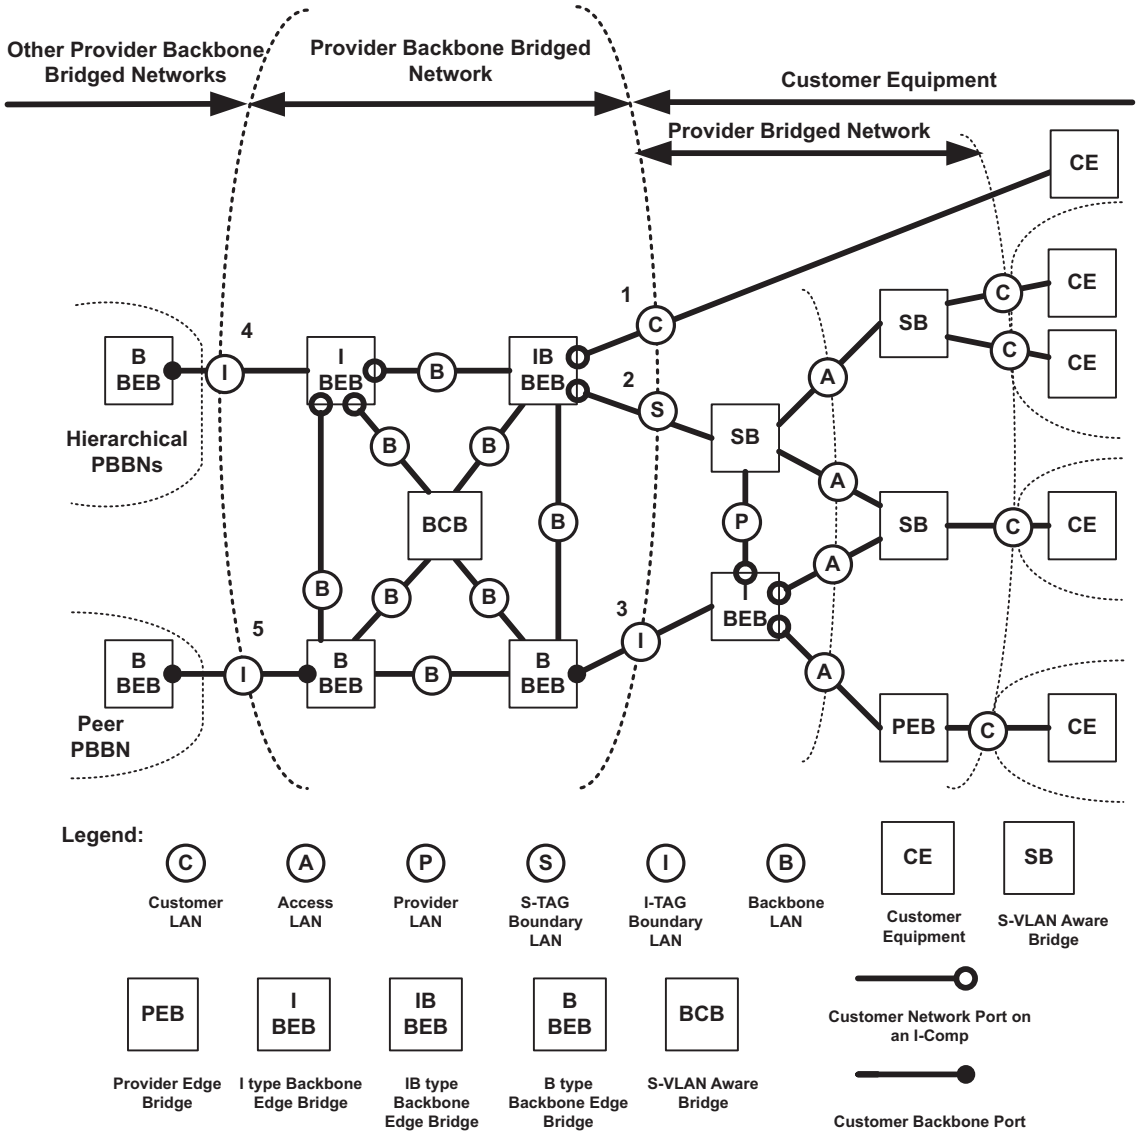

Figure 26-1—PBBN example

The interface between a BEB and a Provider Bridge is a CNP of an I-Component as specified in 6.10. The interfaces between BEBs and BCBs and between BCBs and BCBs are PNPs. In Figure 26-1, these interfaces are over LANs labeled S and B. The interfaces between B-BEB and I-BEBs, or between B-BEBs in different PBBNs, are over LANs labeled I. All exterior interfaces from a PBBN are over S, I, or C LANs; whereas, all interior interfaces within a PBBN are over B LANs. The S, I, and C LANs (exterior interfaces) are at the boundary between the PBBN and the attached customer networks.

The B LANs (interior interface) are backbone LANs, which interconnect all the PBBs within a PBBN.

Within the network example, BEBs, BCBs, and B LANs are secured so that only the backbone provider operating the PBBN can manage the reception, transmission, and relay of frames between BEBs and BCBs. The arbitrary physical network topology of the PBBN and the connectivity that it provides to support segregated instances of the MAC Service is designed and managed by the backbone provider to meet bandwidth and service availability requirements at the CBPs and PIPs. Application of the service instance ingress and egress rules at these Ports in support of service instance selection and identification ensures that frames cannot be transmitted or received on any backbone service instance by any customer's equipment without prior agreement with the provider.

The active MSTP topology of the PBBN area is separated from the active topology of the customer equipment area. This is accomplished by isolating the MST BPDUs for each customer network from the PBBN at the BEBs that surround the perimeter of the PBBN. The BEBs also stop the propagation of MST BPDUs, used to support the active topology of the PBBN, into the Provider Bridged area. In Figure 26-1, Provider Bridge MST BPDUs are propagated over the A, P, C, and S LANs but not over the I or B LANs, while PBB MST BPDUs are propagated over the B LANs but not over the I, C, A, P, or S LANs.

For Port-based service interfaces, the entire C LAN is treated as a single instance of the MAC Service. The BEBs extend the C LAN over the backbone by mapping all service frames on a single backbone service instance identified by an I-SID. The I-SID used is provisioned by the provider operating the PBBN. The provider sets the I-SID on each BEB port attached to a C LAN that is part of the port based service. The BEBs encapsulate the service frames with an I-TAG, B-TAG, B-SA, and B-DA. During the encapsulation, any C-TAG delivered to the CNP is retained in the encapsulated frame as part of the SDU. The BEBs then map the frames onto a B-VLAN with its B-VID contained in the B-TAG and which interconnects the BEBs provisioned for the service. These new frames are transmitted over the B LANs by the BEBs and by the BCBs that carry the B-VLAN. Since the initial octets of the data conveyed in each backbone frame comprise an S-TAG, the frames may be forwarded by BCBs of the PBBN until they reach the next BEB where they might be de-encapsulated. During de-encapsulation, the B-DA, B-SA, B-TAG, and I-TAG are stripped. The C-DA and C-SA from the I-TAG will become the DA and SA transmitted to the receiving C LAN. If the encapsulated SDU contains a C-TAG, it becomes the outside tag as the frame is transmitted to the receiving C LAN.

For S-tagged service interfaces, each instance of MAC Service is carried over the S LANs on one or more S-VLANs. The BEBs preserve the S-VLAN over the backbone by mapping them onto an I-SID and in the case of S-VLAN bundling carrying the S-TAG. This operation is performed by the backbone provider operating the PBBN by configuring the VIP-ISID on each BEB attached to an S LAN. The BEB maps the S-VID to I-SID and encapsulates the original service frame with a new I-TAG, B-SA, and B-DA. The BEB then maps the frame onto a B-VLAN, which interconnects BEBs. This new frame is transmitted over the B LANs by the BEBs and by the BCBs. Since the initial octets of the data conveyed in each backbone frame comprise an S-TAG, the frames may be forwarded by BCBs of the PBBN until they reach the next BEB where they might be de-encapsulated.

For I-tagged service interfaces, each instance of MAC Service is identified by an I-SID value carried over the I LAN in an I-TAG. The BEB maps the frame onto a B-VLAN, which interconnects BEBs. This new frame is transmitted over the B LANs by the BEBs and by the BCBs. Since the initial octets of the data conveyed in each backbone frame comprise an S-TAG, the frames may be forwarded by BCBs of the PBBN until they reach the next BEB where they might be de-encapsulated.

B-MAC addresses are used to identify the destination BEB's PIP. These B-MAC addresses are learned by each PBB as frames are exchanged over B-VLANs. To perform the encapsulation and de-encapsulation of service frames, BEBs use the connection identifier stored in the FDB (see 8.8) to correlate C-MAC addresses to B-MAC addresses. At startup, the BEBs have not learned the B-MAC or C-MAC addresses yet. When the B-MAC address is unknown, the BEB encapsulates the service frames using the Default

Backbone Destination address. The same holds true for the service frames having a group or broadcast destination address. An individual B-DA is used for forwarding unknown or group frames when the service is point-to-point and where the far end individual address is known. Both the B-MAC and C-MAC addresses are learned by the provider BEB (see Clause 8).

Frames containing encapsulated service data are carried within the B-VLANs created over the PBBN. It is also possible to carry unencapsulated S-VLAN traffic in the PBBN core by allocating some of the PBBN VID space to S-VLANs. The B-VLAN determines the route that the frames will take and limits broadcasting within the backbone. The B-TAG is added to the frame at the CBP. The selection of B-VLAN used to form the B-TAG is determined by the configuration of the CBP Backbone Service Instance table. This table maps I-SIDs to B-VIDs and is created as part of service provisioning.

If a BEB's PIP receives a B-MAC Frame whose B-SA is the same as the B-MAC address of the PIP, then a loop exists through the BEBs. Optionally, the BEB may use this condition for loop detection.

26.3 B-VLAN connectivity

The B-VLAN topology of each B-VLAN is established by the mechanisms introduced in 7.1 and Figure 7-1. The backbone provider can use and configure MSTP to provide a number of independent spanning tree active topologies and can assign each B-VLAN to one of these active topologies to best use the resources in the network. MVRP running in the context of each spanning tree active topology configures the extent of each B-VLAN to the subset of that active topology necessary to support connectivity between the customer points of attachment to the instance of MAC Service provided, and can reconfigure that connectivity as required if the spanning tree active topology changes.

The operation of MSTP within a Backbone Provider's network is independent of the operation of any spanning tree protocol within attached provider or customer networks. This is achieved by removing all MST BPDUs received or to be transmitted at the service access interfaces.

The operation of MVRP within a PBBN is independent of the operation of any configuration protocol within attached customer networks. The Provider Bridge MVRP address (Table 8-1) is used as the destination address of all MRPDUs transmitted in support of the MVRP Application. Frames received by CBPs and addressed to the Customer Bridge MVRP address (Table 10-1) are subject to service instance selection and relay in the same way as service frames. The MVRP Administrative Control for each B-VLAN is either Registration Fixed (New Ignored) or Registration Forbidden on all CBPs, so no information is received from any BEB MVRPDU that has been erroneously transmitted by a customer system.

26.4 Backbone addressing

When customer frames enter a PBBN they are encapsulated by the addition of B-MAC addresses and the creation of an I-TAG. The encapsulation is the result of the actions of a PIP as specified in 6.10. The PIPs represent the endpoints of a backbone service instance, and the B-MAC addresses identify these endpoints. (More specifically the VIPs of the PIP represent the endpoints of a backbone service instance, and the combination of the B-MAC addresses and the I-SID identify these endpoints. Since the I-SID identifies which VIP of a PIP is the Backbone Service Instance endpoint, the B-MAC address need only identify the PIP. Therefore, all VIPs of a PIP can share the same MAC address.) This encapsulation ensures that only I-components learn C-MAC addresses, while B-components and Bridges in the PBBN core learn only B-MAC addresses.

The B-SA of an encapsulated frame identifies the PIP that performed the encapsulation and is referred to as the PIP MAC address. For a PIP that connects to an external LAN, this is the address of the PIP itself. For a PIP that has an internal connection to a CBP in the same BEB, this can be any address that results in delivering received I-tagged frames to the I-component, such as the Bridge address of that I-component.

When the PIP MAC address is also used by CFM MPs instantiated on the PIP, there are additional constraints on the uniqueness of that address (26.4.3).

The B-DA of an encapsulated frame identifies the PIP(s) to which the frame should be delivered. The default value for the B-DA is the Backbone Service Instance Group address constructed by concatenating the three octet OUI shown in Table 26-1 with the three octet I-SID, and asserting the I/G bit in the first octet of the resultant value to signify a group MAC address. In a Backbone Service Instance Group address formed in this way, the OUI value is encoded in the first three octets of the address, with the most significant octet of the OUI encoded in the first octet, with the I/G bit (the LSB) set, and the least significant octet of the OUI encoded in the third octet; the most significant octet of the I-SID is encoded in the fourth octet of the address and the least significant octet of the I-SID in the sixth octet.

Table 26-1—Backbone Service Instance Group address OUI

Name	Value
IEEE 802.1Q Backbone Service Instance Group address OUI	00-1E-83

NOTE—Table 26-1 uses the Hexadecimal Representation specified in IEEE Std 802.

When the B-DA of a frame is the Backbone Service Instance Group address, the nominal behavior of the PBBN is to deliver the frame to all CBPs reachable within the B-VLAN to which the backbone service instance is mapped. Filtering based on I-SID by the egress CBP ensures that frames are not transmitted by CBPs that are not part of the backbone service instance. Flooding frames throughout the B-VLAN and filtering at egress provides the correct connectivity for the backbone service instance, but may result in inefficient use of PBBN resources. More efficient frame delivery can be achieved by configuring Static Filtering Entries in the backbone Bridges, or using MMRP to create MAC Address Registration Entries, that restrict the delivery to just the endpoints of the backbone service instance. More efficient delivery can also be achieved by learning individual B-MAC addresses at a PIP, and in some cases by configuring the CBPs to translate the Backbone Service Instance Group address.

26.4.1 Learning individual backbone addresses at a PIP

Individual backbone addresses are learned by means of the connection_identifier parameter generated by the PIP and stored in the FDB. For each received frame, the PIP includes in the EM_UNITDATA.indication a connection_identifier parameter that identifies the backbone source address of the frame. When the I-component Learning Process creates or updates a Dynamic Filtering Entry for a Customer Source MAC address (C-SA) of a frame received through a PIP, it stores the connection_identifier parameter of the EM_UNITDATA.indication for that frame. The connection_identifier parameter is included in the EM_UNITDATA.request for subsequent frames destined to that customer address. Within the PIP, the connection_identifier determines the individual backbone address associated with the customer address. This individual address is then used as the B-DA in place of the Backbone Service Instance Group address.

When a backbone service instance includes only two VIPs, it is possible to use a learned individual backbone address as the default B-DA instead of the Backbone Service Instance Group address. This is accomplished by configuring the AdminPointToPointMAC parameter for the VIP to ForceTrue, which results in the operPointToPointMAC parameter having a value of TRUE. In this case, the PIP copies the B-SA of frames received for that VIP (i.e., the individual MAC address of the peer PIP) to the Default Backbone Destination parameter of the VIP. Subsequent frames transmitted by the PIP on that backbone service instance will then use the individual MAC address of the peer PIP as the B-DA even if the C-DA is unknown or broadcast. Enabling the enhanced filtering criteria (8.7.2) on a VIP will prevent the I-component from creating Dynamic Filtering Entries for C-MAC addresses unnecessarily when the backbone service instance is point-to-point and the S-VLAN that maps to the backbone service instance has only the VIP and one CNP in its member set.

When the enableConnectionIdentifier of a VIP is set to FALSE, the connection_identifier is kept to a NULL value and correspondingly the B-DA used by frames associated with this VIP is always the Backbone Service Instance Group address.

26.4.2 Translating backbone destination addresses at a CBP

In some cases, when the B-DA is the Backbone Service Instance Group address it may be advantageous that the CBP translate this to a different address. Examples where such translation may be useful include the following:

a) When a backbone service instance has only two endpoints within a PBBN, the Backbone Service Instance Group address may be translated at the ingress CBP to the individual address of the egress CBP.
b) When multiple backbone service instances connect the same set of CBPs, the ingress CBP may translate the Backbone Service Instance Group address to a single group address chosen for the set of backbone service instances.

These translations can be accomplished by configuring the Default Backbone Destination parameter in the service instance table of the CBP (6.11). Whenever an ingress CBP is configured to translate the B-DA, the egress CBP must be configured to translate the B-DA back to the Backbone Service Instance Group address. This allows multiple PBBNs connected through Peer E-NNIs to use addresses local to each PBBN.

The CBP is also capable of translating the I-SID on frames entering and exiting the PBBN. This allows the values of the I-SID to be local to a PBBN. If the B-DA of the frame is the Backbone Service Instance Group address and the CBP translates the I-SID, the CBP will also reconstruct the Backbone Service Instance Group address using the new value of the I-SID.

26.4.3 Backbone addressing considerations for CFM MPs

Possible placement of CFM shims in a PIP and a CBP are shown in Figure 26-2. In the PIP, these include MPs to monitor backbone service instances (identified by I-SIDs) in the PBBN, as well as MPs to monitor service instances (identified by VIDs of S-VLANs) in the attached PBNs. In the CBP, these include MPs to monitor backbone service instance (identified by I-SIDs) in the PBBN, as well as MPs to monitor B-VLANs in the PBBN. All of these MPs are assigned individual addresses subject to the constraints specified in 19.4; however, there are additional considerations for the addresses used by MPs in PIPs and CBPs.

In a PIP, the individual address assigned to the backbone service instance-level MPs must be unique within the PBBN. The individual address assigned to the S-VLAN-level MPs must be unique within the set of PBNs interconnected by any backbone service instance supported by the PIP. Therefore, these two groups of MPs may use a common address that is globally unique; however, they may need distinct addresses if local addressing is used in the PBBN.

In the CBP, both the backbone service instance-level MPs and the B-VLAN-level MPs require an individual address that is unique within the PBBN. Therefore, these two groups may use a common address whether it is a global or local address.

26.5 Detection of connectivity loops through attached networks

The transmission and reception of MST BPDUs through CNPs will detect accidental direct connection of those ports. A backbone provider cannot rely on any customer network relaying such frames, and should develop a policy and mechanisms to deal with potential data loops that can arise if the attached customer systems do not operate their own instance or instances of a spanning tree protocol.

A bridged network can be redundantly attached to a PBBN by the means of several Layer Two Gateway Ports (13.40). By way of communication within their region and without any influence from the PBBN, those ports will provide connectivity to the PBBN through a single Layer Two Gateway Port, thus avoiding any bridging loop between the PBBN and the network.

NOTE 1—Use of the restrictedRole parameter at ingress ports ensures that receipt of BPDUs addressed to the Provider Bridge Group address cannot disrupt internal connectivity within the PBBN.

NOTE 2—Specification of PBBN policies, mechanisms, and heuristics used to detect or minimize the impact of data loops created by customer systems is not addressed by this standard. They can include, but are not limited to, bandwidth limitation, charging policies, detection of the repetitive movement of the apparent location of customer stations, and customer agreement to allow the use of PBBN loop detection protocols by not filtering the associated frames.

NOTE 3—A data loop is not the only possible cause of excess bandwidth consumption by a given customer of a PBBN, and the PBBN is usually required to meet service guarantees to other customers irrespective of the cause of the excess bandwidth demand. Data loops are not a unique threat to satisfactory overall network performance. Their distinct characteristic is consumption of discretionary bandwidth without benefiting any customer. The customer that creates the loop can suffer particularly serious network degradation or excess cost as the PBBN limits the total bandwidth consumed by that customer. It is therefore in the interests of each individual customer and the PBBN to raise service satisfaction by preventing and detecting loops.

26.6 Scaling of PBBs

For PBBN deployments, it is important to be able to interconnect PBBNs operated by different organizations. The interfaces between PBBNs are examples of the MEF Forum External Network to Network Interface (E-NNI) referred to in the MEF reference model (section 7.2 and Figure 3 of MEF 4 [B51]). E-NNIs for interconnection of PBBNs can be further classified into two types: hierarchal interconnect and peer interconnect. Examples of hierarchal and peer interconnects are depicted in Figure 26-1 at the interfaces marked 4 and 5.

26.6.1 Hierarchal PBBNs

The hierarchal interconnect connects the PBBNs in a leveled hierarchy. In this interconnect model one PBBN acts as a second-level (n + 1) PBBN to a first-level (n) PBBN. This model allows scaling the number of services by additional hierarchal level. Each level of a hierarchal interconnect adds an additional encapsulation layer.

In the hierarchical model, the (n + 1)-level PBBN carries the n-level PBBN B-VLANs as services in the same manner that the first-level PBBN carries the customer S-VLANs as services. In this model an S-VLAN is presented to a level n PBBN for transport. The PBBN transports the S-VLAN as an instance of MAC Service within a B-VLAN generated by the n-level PBBN. The n-level PBBN is connected to an (n + 1)-level PBBN over a hierarchal E-NNI interface. The (n + 1)-level PBBN carries B-VLANs from the attached n-level PBBN as service instances in (n + 1)-level B-VLANs through the (n + 1)-level PBBN.

Since each hierarchal level requires an additional encapsulation, the nesting depth is limited by the maximum defined frame length for the MAC type used.

26.6.2 Peer PBBNs

The peer interconnect between PBBNs results in a flat service space that does not increase the encapsulation nesting depth. The network scales the number of services over the combined PBBNs by service localization. Further localization and scaling of services is supported by the I-SID filtering functions in addition to the optional I-SID translation functions of the CBP interfaces on each side of the peer E-NNI (6.11). Services that are limited in extent to a single PBBN do not consume any resources within the other connected PBBNs.

The peer interconnect will extend backbone service instances across the peer connected PBBNs. In the peer interconnect a service instance in PBBN A is connected to a service instance in PBBN B by the peer E-NNI between the PBBNs. The peer E-NNI is formed by an I-tagged Service Interface between two CBPs (6.11), one in each of the peer PBBNs. The I-SID used over the E-NNI must be agreed to mutually by both providers. At each end of the E-NNI the CBP may optionally translate the I-SID (and the B-DA if it is the default multicast address generated from the I-SID) used over the E-NNI to a new I-SID for use within the PBBN. The CBPs also map the I-SID to a B-VLAN within the PBBN, as no B-TAGs are transmitted across the peer interconnect.

26.7 Network management

Management of a PBB is directly under the control of the backbone provider. PBN customers shall not have access to managed objects related to elements of PBBs within the PBBN.

In SNMP management systems, this can be realized by implementing one management entity acting as an agent in the Provider Bridge and separating the management views that include customer networks information from the management views that include provider networks information using the mechanisms defined by the SNMP management framework in IETF RFC 3411.

26.8 CFM in PBBs

CFM (Clause 18 through Clause 22) may operate over LANs, C-VLANs, S-VLANs, B-VLANs, and backbone service instances identified by I-SIDs. CFM Maintenance domain Endpoints (MEPs) and Maintenance domain Intermediate Points (MIPs) may be inserted at any of the EISS service interfaces described by 6.9, 6.10, and 6.11, at the ISS service interface described in IEEE Std 802.1AC, and within the EISS and Backbone Service Instance Multiplex Entity described in 6.17 and 6.18.

Within a PBBN, the encapsulation performed by PIPs also encapsulates CFM frames sourced by customers attached to CNPs. Encapsulation of S-VLAN and C-VLAN CFM frames hides them from the PBBN enabling a new set of independent MD levels to be defined in the PBBN for CFM, which may be used for managing B-VLANs spanning between the B-components and BCBs of the PBBN, and over LANs that span between PBB ports. In addition, the backbone may support MAs per backbone service instance that are identified by I-SIDs and span between the PIPs and CBPs of I-components and B-components of the PBBN. A full set of eight maintenance levels exists within each PBBN for use by B-VLAN CFM frames. The Backbone Service Instance CFM frames may extend over a E-NNI, therefore providing eight levels of Backbone Service Instance CFM for the extended backbone, which includes all peer connected PBBNs. All eight levels of CFM frames generated in customer networks are carried over the backbone as encapsulated data and may be used by customer networks. Another eight maintenance levels exist for the LANs for which no frames are untagged. This may be the case for the PNP-PNP LAN links. The CFM stacks for the PIP and CBP are depicted in Figure 26-2. The stacks for the CNP and PNP are as depicted in 22.1.1.

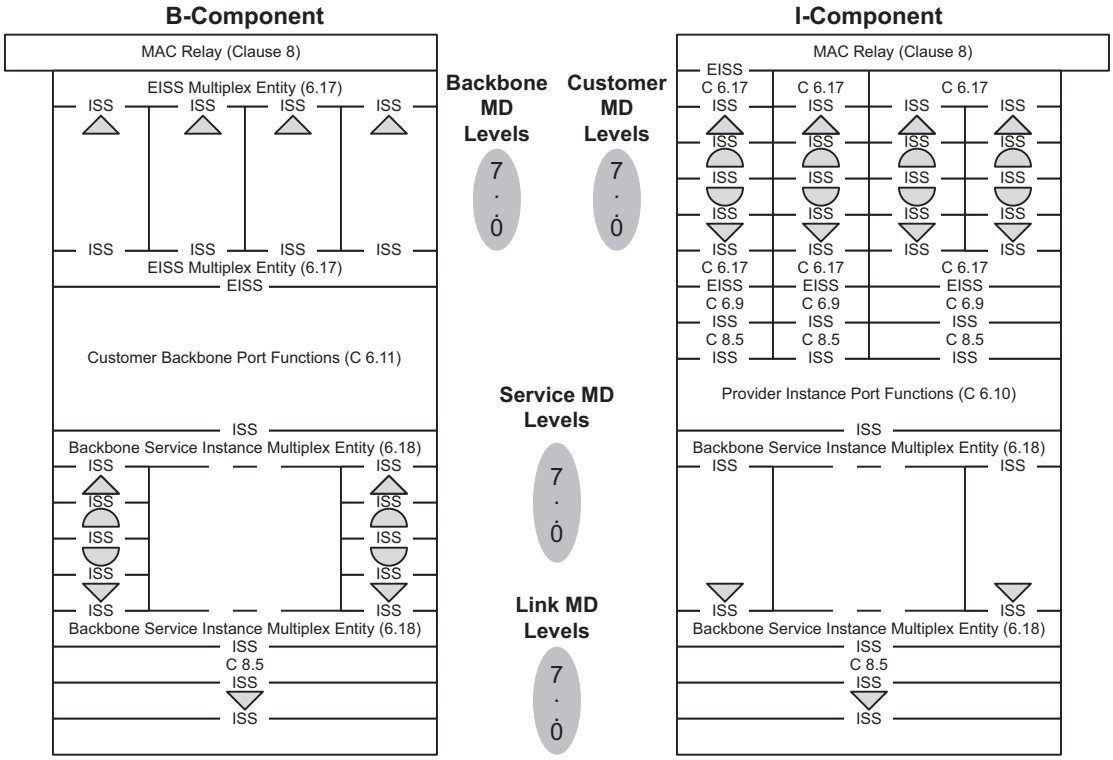

Figure 26-2—CFM shim model

Figure 26-3 and Figure 26-4 show possible MAs at the three types of PBBN service interfaces described in 25.3, 25.4, and 25.5, respectively. These three interfaces are depicted in Figure 26-1, where they are labeled 1, 2, and 3. Figure 26-5 and Figure 26-6 show possible MAs at the two types of PBBN E-NNI interfaces, which are described in 26.6.1 and 26.6.2, respectively. These two types of E-NNIs are depicted in Figure 26-1, where they are labeled 4 and 5. The MAs indicated in Figure 26-3 through Figure 26-6 are example MAs for each PBBN service interface type and PBBN E-NNI type. Typically not all these MAs would be supported within any given PBBN since some MAs illustrated provide redundant capabilities and since the selection of MAs will depend on the service-level agreements used for a particular service, on the operational environment of a particular PBBN and on the equipment used in the particular PBBN.In these figures, four distinct categories of MAs are depicted. These are the S-VLAN and C-VLAN MAs, the Backbone Service Instance MAs, the B-VLAN MAs, and the LAN MAs. Each of these four classes of MAs is associated with independent sets of MDs introducing four independent sets of eight maintenance levels. The selection of which levels for each of these MDs to use in a particular network depends on the specific network implementation. The S-VLAN MAs are only visible within the I-component where customer frames are un-encapsulated. Customer CFM frames are encapsulated along with the other customer frames at the VIPs within the I-component. Once the S-VLAN CFM frames are encapsulated, they appear just like any data frame within the PBBN; therefore, they do not activate any CFM functions within the PBBN past the VIPs. The Backbone Service Instance CFM frames may optionally be generated at the Backbone Service Instance Multiplex Entity within the PIP or CBP. These CFM frames are only visible within the PBBN where the I-TAG is being processed, that is at the CBP and at the PIP. Each Backbone Service Instance MD may be assigned to one of eight maintenance levels. Since the Backbone Service Instance CFM maintenance domain may extend over E-NNI boundaries, these eight levels extend over all interconnected PBBNs until they are terminated at a VIP. B-VLAN MAs manage the B-VLANs within a single PBBN. The B-VLAN MDs have a new set of eight maintenance levels, which are separate for each PBBN and never extend out of

the PBBN. Finally, the LAN links within a PBBN (PIP to CBP, PNP to PNP), between two PBBNs (CBP to CBP, PIP to CBP) and entering/egressing the PBBN (to/from CNP) may optionally be monitored by LAN link MAs, generated/terminated within the PIP, CBP, PNP, and CNP. LAN link MAs are typically confined to the LAN link.

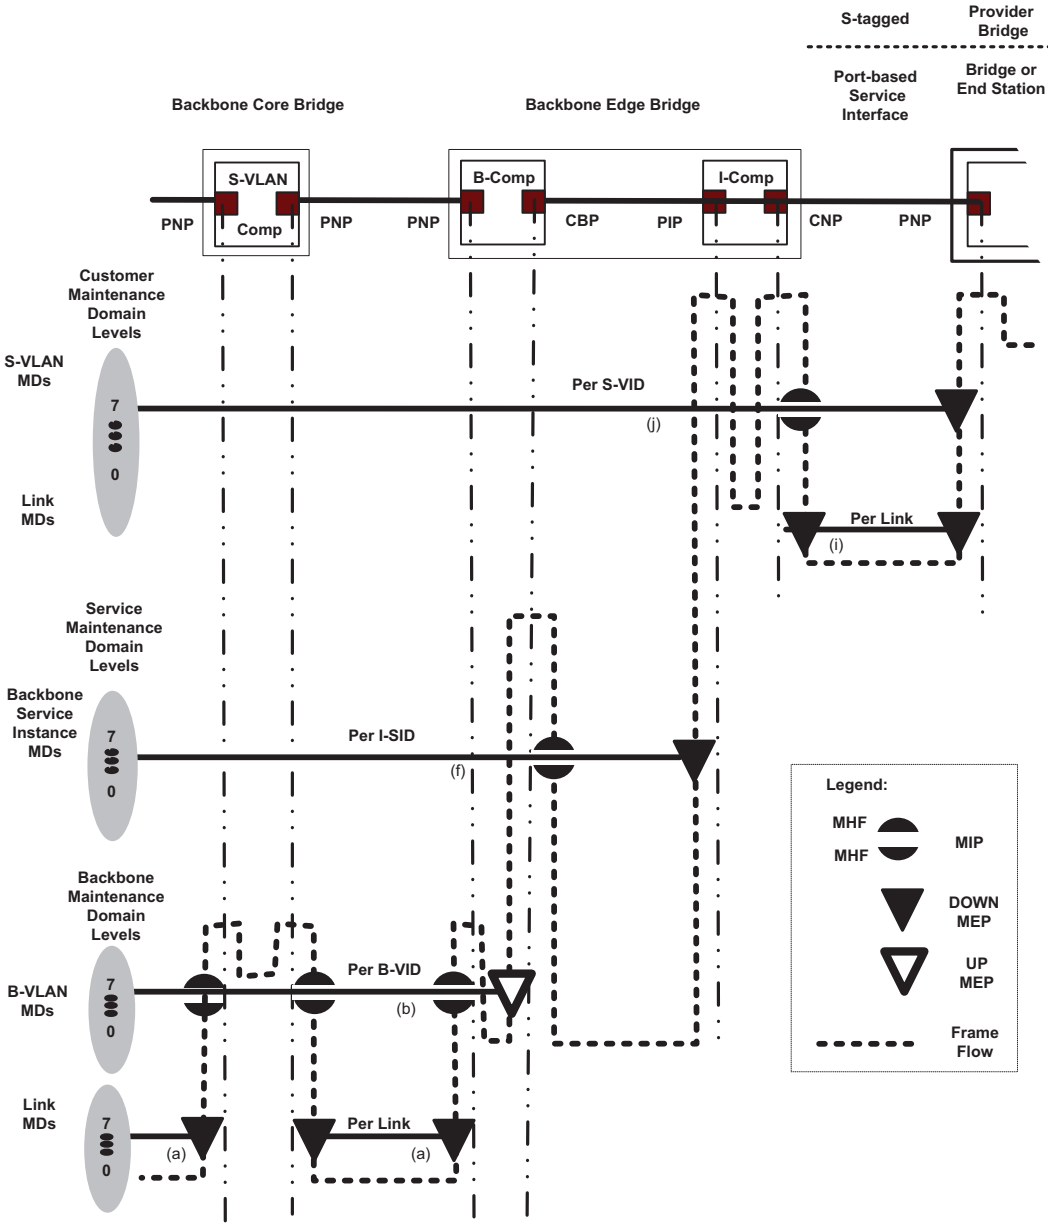

Figure 26-3—CFM example applied to a Port-based and S-tagged service interface

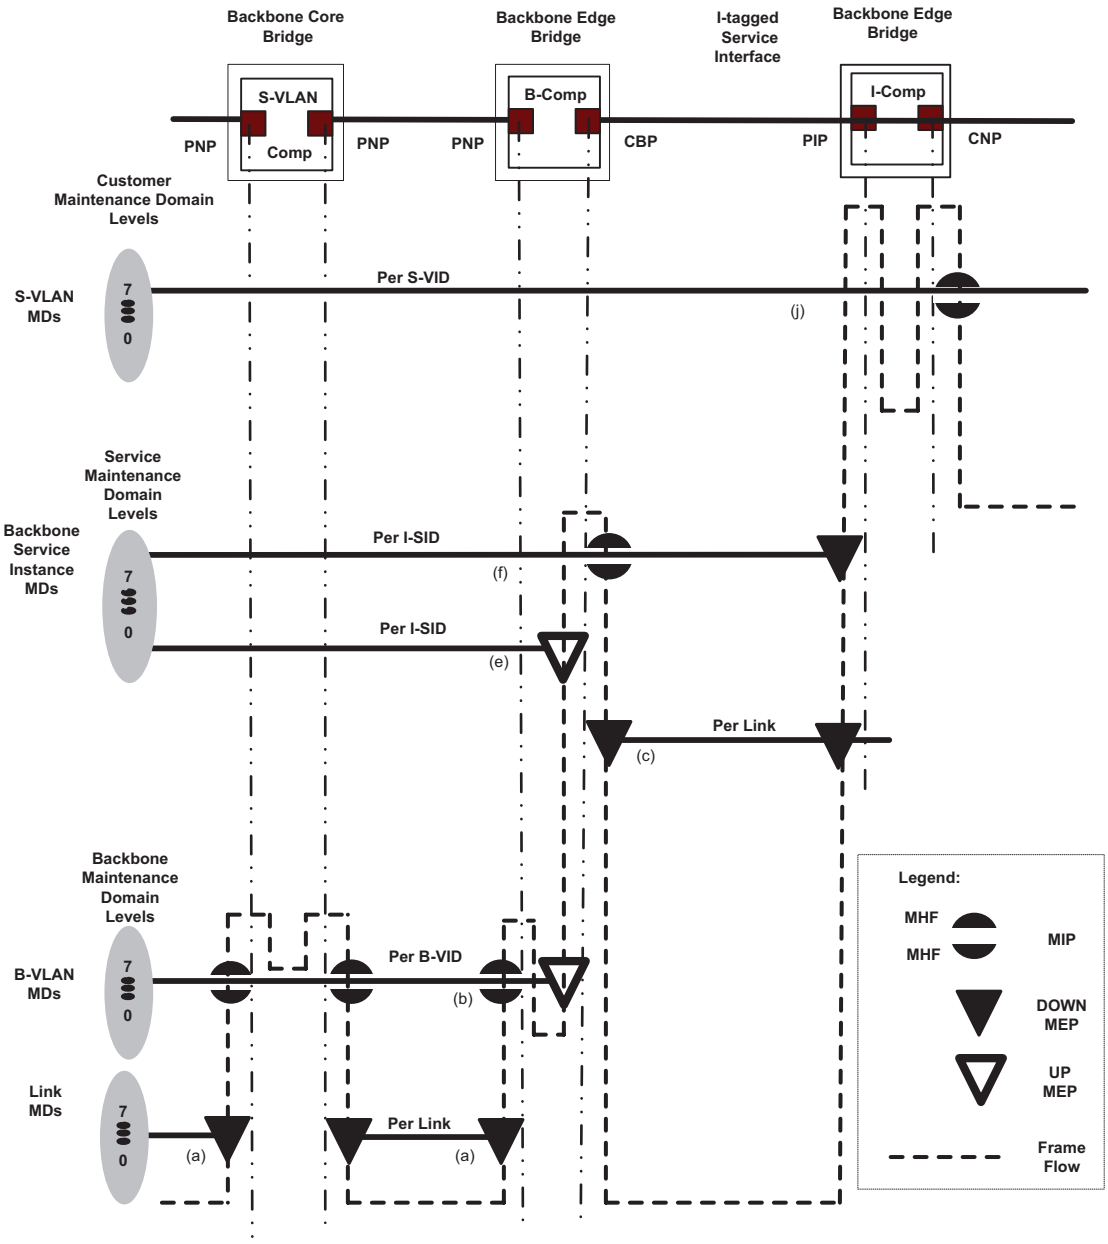

Figure 26-4—CFM example applied to an I-tagged Service Interface

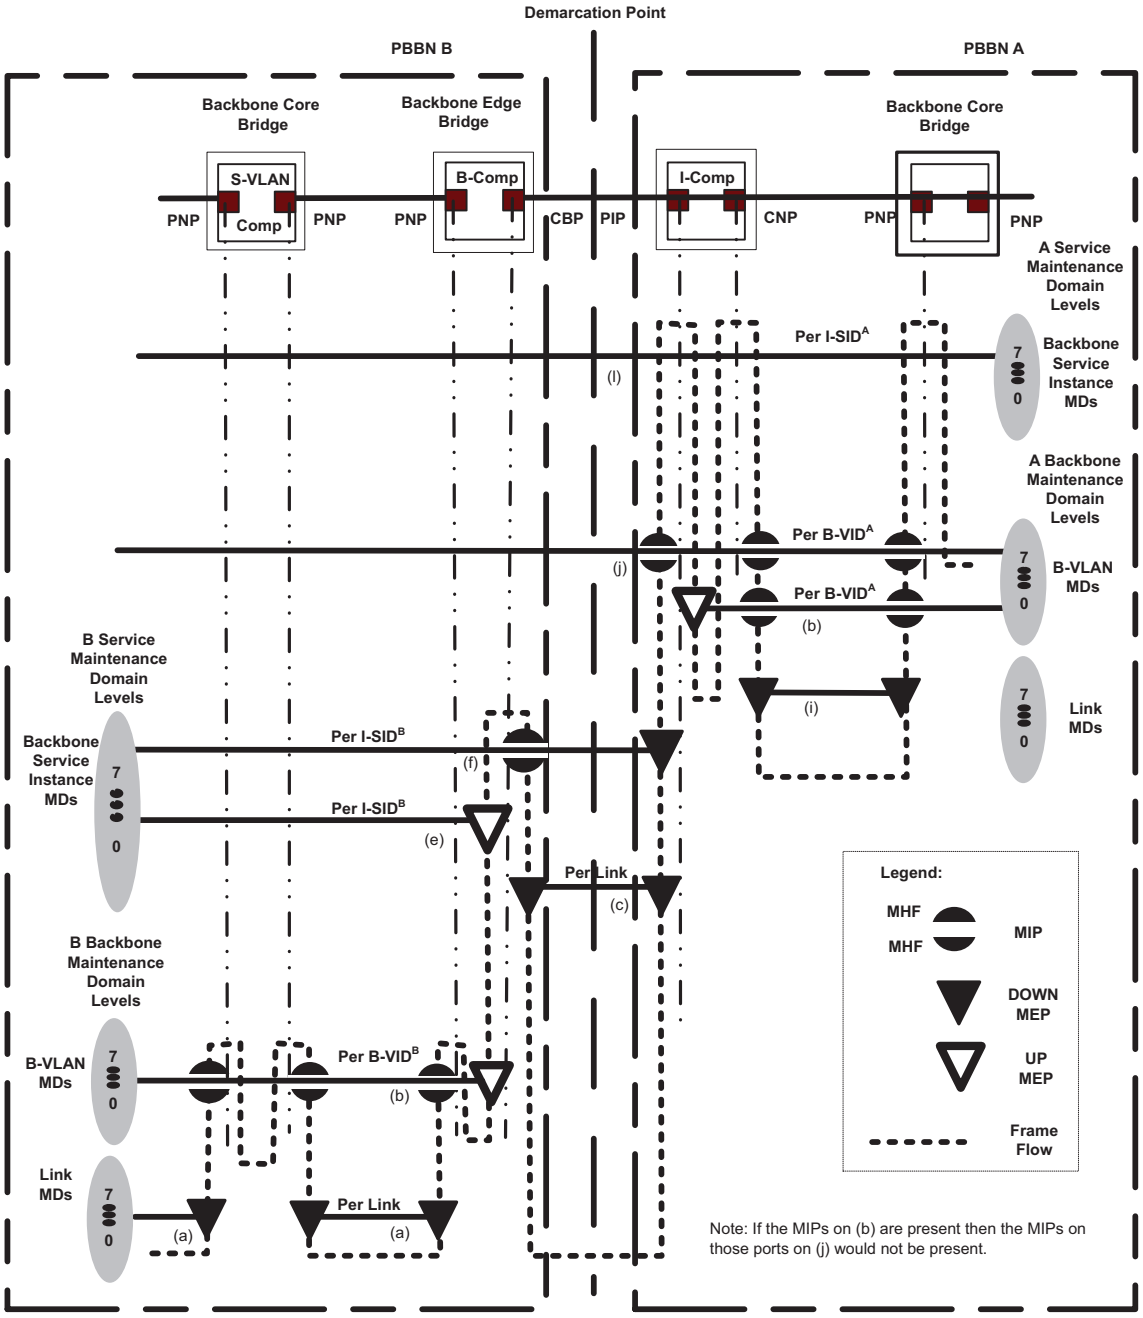

Figure 26-5—CFM example applied to a hierarchal E-NNI, CBP-PIP Demarc

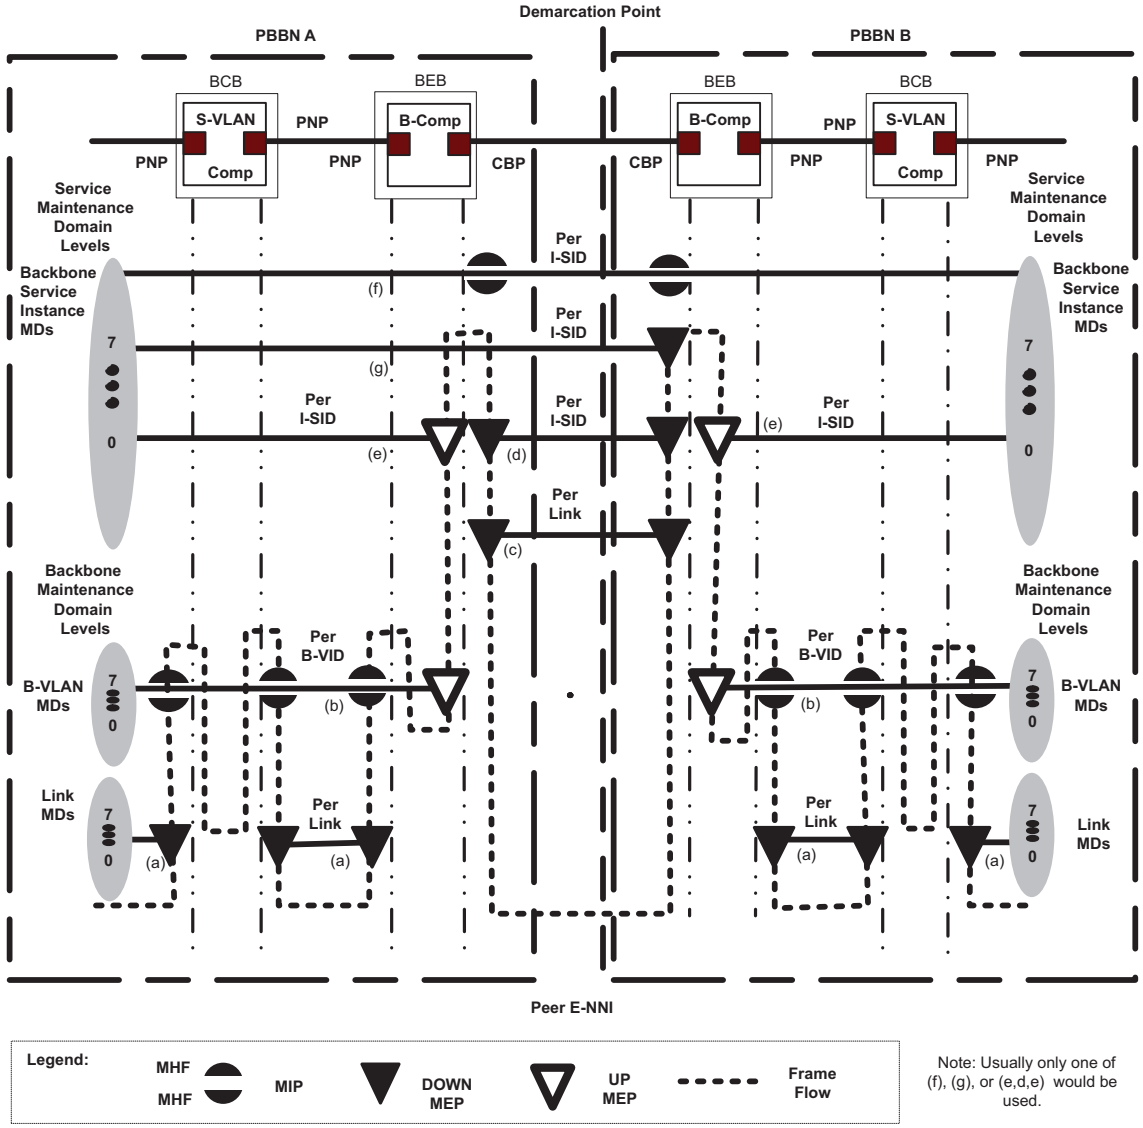

Figure 26-6—CFM example applied to a peer E-NNI, CBP-PIP

26.8.1 CFM over Port-based and S-tagged service interfaces

Figure 26-3 shows example MAs for the Port-based or S-tagged service interface described in 25.3 and 25.4 and depicted in Figure 26-1 labeled 1 and 2.

MAs (a) and (b) illustrated in Figure 26-3 through Figure 26-6 are used to monitor the PBBN core. Each PBBN has an independent backbone MD-level space. MAs (a) and (b) are assigned Backbone Maintenance Levels from the backbone MD-level space of their PBBN in the same manner used to assign S-VLAN MAs described in Clause 22. The MAs (a) are used to monitor each individual LAN that interconnects PNPs. The MAs (b) monitor specific B-VLANs. The B-VLAN monitoring, illustrated in the example, begins at the up MEP located at the top of the CBP. A given B-VLAN may exit a B-component on multiple PNPs, each of which may have a MIP on MA (b) if desired.

MAs (i) and (j) illustrated in Figure 26-3 through Figure 26-6 are two possible customer MAs. Attached customers have an independent customer MD-level space. MAs (i) and (j) are assigned Customer Maintenance Domain Levels from their customer MD-level space in the manner used for S-VLAN MAs described in Clause 22. The MAs (i) monitor the links between the customer equipment and the CNP or the PBBN. At the Port-based or the S-tagged service interface, MAs (i) may be terminated by the provider by an MEP at the CNP and used to monitor the customer's access link. The MAs (j) monitor the service instance from the customer over the PBBN. MAs (j) extend between all the customer attachments of the extended PBBN, passing through any PBBN E-NNI interfaces. At the VIPs located at the edge of the extended PBBN, the CFM frames for MA(j) will be mapped to/from an I-SID and carried over the extended PBBN as encapsulated frames. These CFM frames are encapsulated by the PBBN in the same manner as data frames. The encapsulation makes them invisible to any MPs within the extended PBBN.

In the case of a Port-based service interface, the MA(j) CFM frames are untagged or C-tagged over the interface formed between the CNP and the customer equipment. In this case, the MA(j) CFM frames have an S-VID assigned from the PVID at the CNP, which will be carried to the VIP within the I-component. In the case of an S-tagged service interface, the MA(j) CFM frames are untagged, C-tagged, or S-tagged over the interface formed between the CNP and the customer equipment. In this case, the MA(j) CFM frames have the S-VID carried over the service interface or, if the CFM frame is not S-tagged, it will have an S-VID assigned from the PVID of the CNP.

MA (f) depicted in Figure 26-3 through Figure 26-6 is used for backbone service instance management. MAs (f) are within the Backbone Service Instance MD-level space, which is shared over the entire extended PBBN. MAs (f) are assigned Service Maintenance Domain Levels from this Backbone Service Instance MD-level space. The MEPs for MA(f) are formed at the PIP within the Backbone Service Instance Multiplex Entity (6.18) as seen in Figure 26-2. MA(f) may have MIPs located in the CBP also formed by a Backbone Service Instance Multiplex Entity as depicted in Figure 26-2.

26.8.2 CFM over I-tagged Service Interfaces

Figure 26-4 shows possible MAs for the I-tagged service interface described in 25.5 and depicted in Figure 26-1 labeled 3. The MAs (a) and (b) in Figure 26-4 are used for PBBN core monitoring as described in 26.8.1.

MAs (c) in Figure 26-4, Figure 26-5, and Figure 26-6 are used to monitor the link between the PIP and CBP. The MAs (c) CFM frames are unique among the other CFM frames because they are transmitted without an I-TAG over the CBP to PIP LAN.

MAs (f) depicted in Figure 26-4 are used for service management as described in 26.8.1. In an I-tagged service interface, MAs (f) have an MEP in the customer network located at the Backbone Service Instance Multiplex Entities (6.18) of the customer PIP and may have MIP within the extended provider network located at the Backbone Service Instance Multiplex Entities of the CBPs. The provider may use MAs (e) to monitor each service instance by placing a MEP at the Backbone Service Instance Multiplex Entities of the CBP. The backbone service instance-level space is shared between the customer and provider who must agree on the levels used for provider and customer Backbone Service Instance CFM messages.

Customer S-VLAN MAs (j) are encapsulated by the customer equipment and are indistinguishable from data within the PBBN.

26.8.3 CFM over hierarchal E-NNI

Figure 26-5 shows possible MAs for the hierarchal E-NNI described in 26.6.1. In Figure 26-1 the hierarchal E-NNI labeled 4 depicts an E-NNI with the demarcation point between the CBP and PIP. Example MAs for a hierarchal E-NNI with demarcation between CBP and PIP are illustrated in Figure 26-5. The MAs (a) and (b) in Figure 26-5 are used for PBBN core monitoring as described in 26.8.1.

The operation of the backbone service instance and LAN MAs (f), (e), and (c) are as described in 26.8.2. Since each PBBN-A B-VLAN MA (j) is mapped into a PBBN-B backbone service instance monitored by MAs (f) and/or (e) the MAs (f) and (e) may be used to monitor the extended B-VLAN from PBBN-A.

MAs (j) are not visible to PBBN-B as described in 26.8.2. The per PBBN-A Backbone Service Instance MAs (l) illustrated in Figure 26-5 are never visible to PBBN-B since they are encapsulated along with the B-VLAN.

26.8.4 CFM over peer E-NNI

Figure 26-6 shows possible MAs for the peer E-NNI described in 26.6.2 and depicted in Figure 26-1 labeled 5. The MAs (a) and (b) in Figure 26-6 are used for PBBN core monitoring as described in 26.8.1. The LAN MAs (c) and Backbone Service Instance MAs (e) and (f) in Figure 26-6 are as described in 26.8.2.

The MAs (f), (g), (d), and (c) extend over the demarcation point between PBBN-A and PBBN-B, while the MAs (e) are within PBBN-A and PBBN-B and do not extend over the demarcation point. The MA (f) is a Backbone Service Instance MA that extends through both PBBN-A and PBBN-B providing monitoring for the service from VIP to VIP. MAs (f) may have a MIP on each side of the demarcation point to allow isolation of a fault to an individual PBBN. The MAs (g) also are Backbone Service Instance MAs that extend over the demarcation point. MAs (g) are launched by PBBN-B at the CBP facing the E-NNI rather than at the service originating VIP and extend to the far edge of PBBN-A. MAs (g) may be used by PBBN-B to monitor the backbone service instance over PBBN-A, but only provides information to PBBN-A on the operation of the backbone service instance over the demarcation point to PBBN-B. The MA (d) is a Backbone Service Instance MA that monitors the service over the demarcation point, but does not provide any monitoring deeper in PBBN-A or PBBN-B. MAs (e) provide internal monitoring of the backbone service instance within PBBN-A and PBBN-B, respectively.

26.9 CFM in a PBB-TE Region

CFM as specified in Clause 18 through Clause 22, provides capabilities useful in detecting, isolating, and reporting connectivity faults in VID-based service instances, backbone service instances, TESIs, and Infrastructure Segments. The list of features that are specifically related to TESIs and Infrastructure Segments is summarized here.

NOTE—MIP function is not supported for an Infrastructure Segment MA. Loopback is supported on Infrastructure Segment MEPs. It is not useful to apply the Linktrace operation to an Infrastructure Segment MA. No extension is made to the Loopback or Linktrace operations supporting their use for an Infrastructure Segment MA. This does not preclude the use of MIPs associated with a PBB-TE MA.

In particular, this subclause summarizes PBB-TE considerations related to the following:

a) Addressing PBB-TE MEPs (26.9.1)
b) TESI identification (26.9.2)
c) PBB-TE MEP placement in a Bridge Port (26.9.3)
d) PBB-TE MIP placement in a Bridge Port (26.9.4)
e) TESI Maintenance Domains (26.9.5)
f) PBB-TE enhancements of the CFM protocols (26.9.6)
g) Addressing Infrastructure Segment MEPs (26.9.7)
h) Infrastructure Segment identification (26.9.8)
i) Infrastructure Segment MEP placement in a Bridge Port (26.9.9)
j) Infrastructure Segment Maintenance Domains (26.9.10)
k) IPS extensions to Continuty Check operation (26.9.11)

26.9.1 Addressing PBB-TE MEPs

The configuration of an MA requires a parameter (or a list of parameters) that associates it with the monitored service. A TESI is identified by the list of ESPs supporting it. Correspondingly, the configuration of a PBB-TE MA, requires the list of the monitored TESI's ESPs, each identified by the 3-tuple <ESP-DA, ESP-SA, ESP-VID> or collectively by the TE-SID (12.14.5.3.2).

The MEPs related to a TESI require the same set of parameters as a VID-based MEP requires, with the following changes:

a) The Primary VID is not writable but is always set to the value of the ESP-VID parameter that corresponds to the MA's ESP that has the MEP's MAC address in its ESP-SA field [item d) in 12.14.7.1.3, 20.9.7].
b) The MAC address of the MEP is the MAC address of the CBP upon which the MEP is operating [item i) in 12.14.7.1.3].

26.9.2 TESI identification

In contrast to VID-based services where the vlan_identifier is used to identify the service, independent ESPs could have the same VID value in their ESP-VID field if some other parameters in their identifying 3-tuples are different. Figure 26-7 depicts such a case where the two ESPs are distinguished by their source addresses. The TESI Multiplex Entity (6.19) allows shims defined for PBB-TE to be instantiated per TESI at a SAP that supports multiple TESIs.

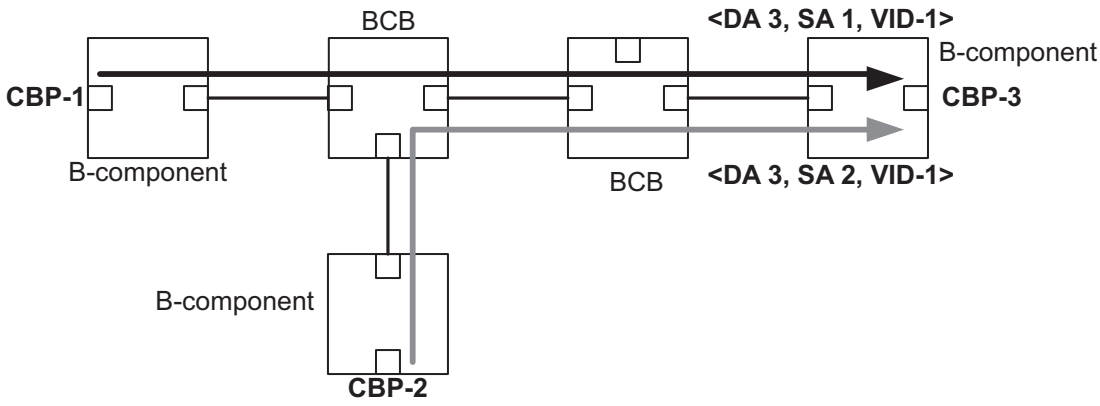

Figure 26-7—Independent ESPs using the same ESP-DAs and ESP-VIDs

26.9.3 PBB-TE MEP placement in a Bridge Port

PBB-TE MEPs are always Up MEPs and can only be placed on CBPs as these correspond to the demarcation points of the ESPs supporting the PBB-TE service. The PBB-TE MEPs are placed between the Frame filtering entity (8.6.3) and the Port filtering entities (8.6.1, 8.6.2, and 8.6.4) in the ESP-VID space identified by the EISS Multiplex Entity (6.17). Since the ESP MAC addresses can be reused by different ESPs, the PBB-TE MEPs need to be further differentiated by the TESI Multiplex Entity (6.19). In principle, separately for each TESI, there can be from zero to eight Up MEPs, ordered by increasing MD Level, from Frame filtering toward Port filtering, even though not more than one MD Level is expected for PBB-TE MAs. Figure 26-8 depicts an example of PBB-TE MEPs on a CBP.

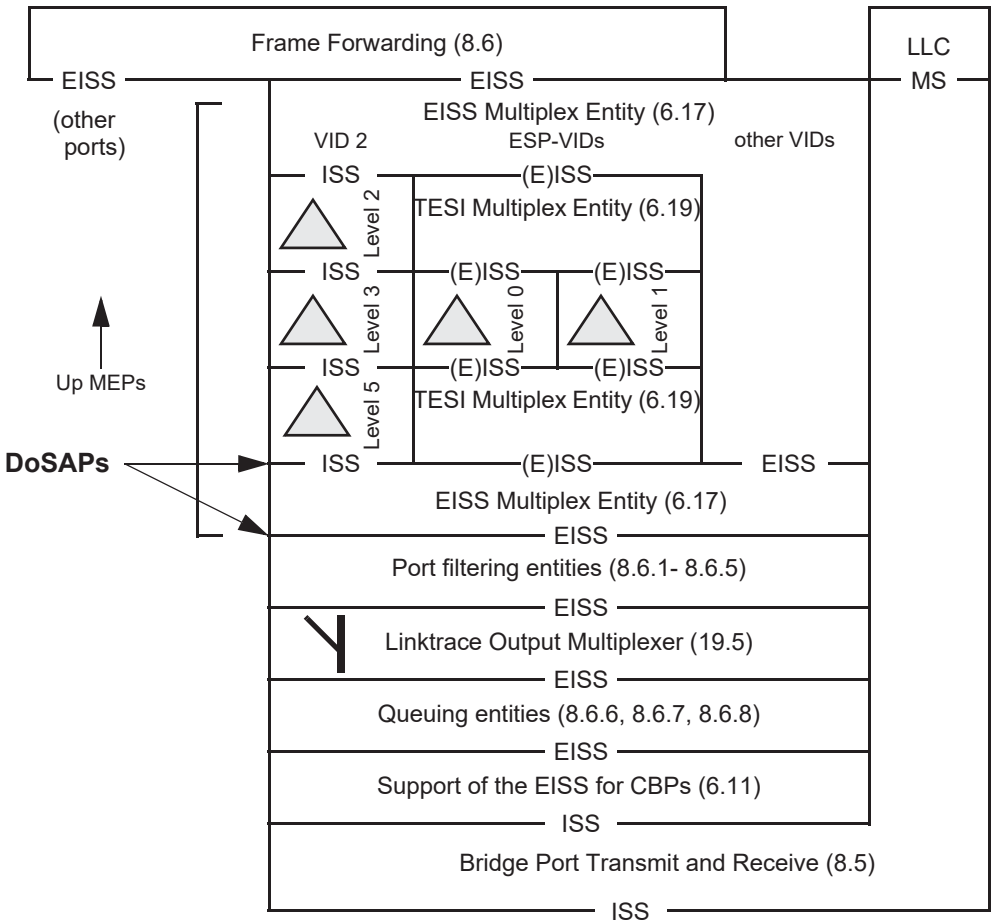

Figure 26-8—PBB-TE MEP placement in a CBP

26.9.4 PBB-TE MIP placement in a Bridge Port

PBB-TE MIPs creation is based on the algorithm described in 22.2.3. PBB-TE MIPs are created per identified ESP-VIDs on PNPs. Figure 22-9 depicts an example of a pair of PBB-TE MHFs on a PNP.

26.9.5 TESI Maintenance Domains

A PBB that is capable of providing TESIs supports a new set of TESI MDs in addition to those described in 26.8. In particular the CFM stacks in Figure 26-2 will need to have TESI MD levels in parallel to the depicted Backbone MD levels for CBPs initiating TESIs while TESI MDs will have to be present in parallel to the Backbone MD levels depicted in Figure 26-3.

26.9.6 PBB-TE enhancements of the CFM protocols

26.9.6.1 Continuity Check protocol in a PBB-TE MA

The Continuity Check protocol is described in 20.1 and the corresponding state machines in Clause 20. The only enhancement required by the PBB-TE MA is in the procedure that is responsible for constructing and transmitting a CCM (20.11.1):

a) The destination_address parameter is set to the MAC address indicated by the value of the ESP-DA field of the ESP having as ESP-SA the MAC address of the MEP emitting the CCM.

PBB-TE MAs may also implement the following enhancements to the Continuity Check protocol:

b) The procedure MEPprocessEqualCCM() on PBB-TE MEPs does not include the check of the MAID on received CCMs [item b) in 20.17.1].

c) PBB-TE MEP's may:

1) Set the Traffic field (21.6.1.4) bit on transmitted CCMs based on information from the Backbone Service Instance table associated with the CBP upon which the MEP is configured. In particular, the procedure xmitCCM() (20.11.1) is performing the additional action to fill the Traffic field with the presentTraffic variable (20.9.8); and

2) Check the Traffic field bit on received CCMs (20.16.13); and

3) Implement the MEP Mismatch state machines (20.26).

All other Continuity Check processes are the same as those for a VID-based MA.

26.9.6.2 Loopback protocol in a PBB-TE MA

The Loopback protocol is described in 20.2 and the corresponding state machines in Clause 20. The enhancements required by the PBB-TE MA are summarized below:

a) The LBMs transmitted by a MEP associated with a PBB-TE MA use as the destination_address parameter, the MAC address indicated by the value of the ESP-DA field of the MA's ESP that has the MEP's MAC address indicated in its ESP-SA field [item a) in 20.31.1]. To enable MIPs to selectively intercept LBMs that are targeting them, the PBB-TE MIP TLV (21.7.5) is inserted as the first TLV [item f) in 20.31.1] in an LBM. The PBB-TE MIP TLV is not included if the LBM destination address in 12.14.7.3.2 is associated with any of the values in the ESP-DA field of the monitored MA's ESPs. The format of the PBB-TE MIP TLV is described in 21.7.5 and is constructed as follows:

1) The MIP MAC address field contains the MAC address of the MIP to which the LBM is targeted [item b) in 12.14.7.3.2].

2) The Reverse VID field contains the parameter provided in item f) in 12.14.7.3.2, which it uses as the vlan_identifier in the replied LBR.

3) The Reverse MAC field is only included if the MEP is associated with a point-to-multipoint TESI. If the MEP is the root MEP, the Reverse MAC field contains the ESP-SA value of any of the point-to-point ESPs in the TESI. If the MEP is a leaf MEP, the Reverse MAC field contains the ESP-DA of the point-to-multipoint ESP in the TESI.

b) LBMs received by PBB-TE MEPs are not processed and are discarded if the received LBM carries a PBB-TE MIP TLV. A PBB-TE MHF forwards all received LBMs except those carrying a PBB-TE MIP TLV containing in their MIP MAC address field the MAC address of the MIP associated with that PBB-TE MHF [item f) in 20.28.1].

c) The destination_address parameter used by LBRs transmitted by PBB-TE MEPs is the value of the ESP-DA of the MA's ESP that has the MEP's own address in its ESP-SA field. In the case of a PBB-TE MHF, the destination_address parameter for the transmitted LBR is:

1) The value carried in the Reverse MAC field contained in the PBB-TE MIP TLV of the received LBM, if this is a group MAC address; otherwise,

2) The value of the source_address of the received LBM.

d) The source_address of LBRs transmitted by PBB-TE MHFs is set to:

1) The destination_address of the received LBM if this destination address is an individual MAC address; otherwise,

2) The value carried in the Reverse MAC field contained in the PBB-TE MIP TLV if the received LBM's destination address is a group MAC address.

e) The vlan_identifier used by LBRs transmitted by PBB-TE MEPs is set to the value of its Primary VID [item d) in 12.14.7.1.3]. The vlan_identifier used by LBRs transmitted by PBB-TE MHFs is set to the value carried in the Reverse VID field contained in the PBB-TE MIP TLV of the received LBM.

All other Loopback processes are the same as those for a VID-based MA.

26.9.6.3 Linktrace protocol in a PBB-TE MA

The Linktrace protocol is described in 20.3 and the corresponding state machines in Clause 20. The enhancements required by the PBB-TE MA are summarized as follows:

a) The LTMs transmitted by a MEP associated with a PBB-TE MA use as the destination_address parameter, the MAC address indicated by the value of the ESP-DA field of the MA's ESP that has the MEP's MAC address indicated in its ESP-SA field [item a) in 20.42.1]. LTMs carry the PBB-TE MIP TLV constructed as follows:
   1) The MIP MAC address field is null.
   2) The Reverse VID field contains the parameter provided in item e) in 12.14.7.4.2, which is used as the vlan_identifier of the replied LTR.
   3) The Reverse MAC field is only included if the MEP is associated with a point-to-multipoint TESI. If the MEP is the root MEP, the Reverse MAC field contains the ESP-SA value of any of the point-to-point ESPs in the TESI. If the MEP is a leaf MEP, the Reverse MAC field contains the ESP-DA of the point-to-multipoint ESP in TESI.

b) No special destination_address validation tests are performed by the ProcessLTM() procedure in the case of PBB-TE MAs [item c) in 20.47.1].

c) The process to identify a possible egress port by an intermediate device that implements a MIP associated with a PBB-TE MA, queries the FDB of the corresponding Bridge, using the destination_address, and the vlan_identifier of the LTM as the parameters for the lookup (20.47.1.2). The LTMs can be further forwarded by PBB-TE MIPs even if the lookup identifies more than one Egress port.

d) Finally an LTR issued by a PBB-TE MP:
   1) Uses as destination_address: the value carried in the Reverse MAC field contained in the PBB-TE MIP TLV of the received LTM, if this is a group MAC address; otherwise, the source_address of the received LTM [item a) in 20.47.4].
   2) Uses as source_address: its MAC address if the LTR is issued by a PBB-TE MEP; otherwise, the destination_address of the received LTM if this is destination address is an individual MAC address; otherwise, the value carried in the Reverse MAC field contained in the PBB-TE MIP TLV of the received LTM [item b) in 20.47.4].
   3) Sets the vlan_identifier parameter to the value carried in the Reverse VID field contained in the PBB-TE MIP TLV of the received LTM [item c) in 20.47.4].

All other Linktrace processes are the same as those for a VID-based MA.

26.9.7 Addressing Infrastructure Segment MEPs

The configuration of an Infrastructure Segment MA requires a parameter identifying the associated Infrastructure Segment. An Infrastructure Segment is composed of a pair of counterdirectional and co-routed Segment Monitoring Paths (SMPs) (26.11.1). Each SMP is identified by an SMP Identifier (SMP-ID). Thus, an Infrastructure Segment is identified by a pair of SMP-IDs that is known as an Infrastructure Segment Identifier (SEG-ID). The SEG-ID is specified on configuration of the associated Infrastructure Segment MA (12.14.5.3.2).

A MEP associated with an Infrastructure Segment requires the same set of parameters required by a VID-based MEP, with the following changes:

a) The Primary VID is not writable but is always set to the value of the SMP-VID parameter that corresponds to the MA's SMP that has the MEP's MAC address in its SMP-SA field [item d) in 12.14.7.1.3].
b) The MAC address of the MEP is the MAC address of the PNP upon which the MEP is operating [item i) in 12.14.2.1.2].

26.9.8 Infrastructure Segment identification

Two SMPs are distinct if their corresponding SMP-ID values (3-tuples) differ in at least one parameter. Thus, independent Infrastructure Segments can be associated with SMPs having identical values of SMP-DA and SMP-VID. Figure 26-9 depicts a case in which two SMPs, having identical values of SMP-DA and SMP-VID, are distinguished by their SMP-SA values. The Infrastructure Segment Multiplex Entity (6.21) allows shims defined for PBB-TE IPS to be instantiated per Infrastructure Segment at a SAP that supports multiple Infrastructure Segments.

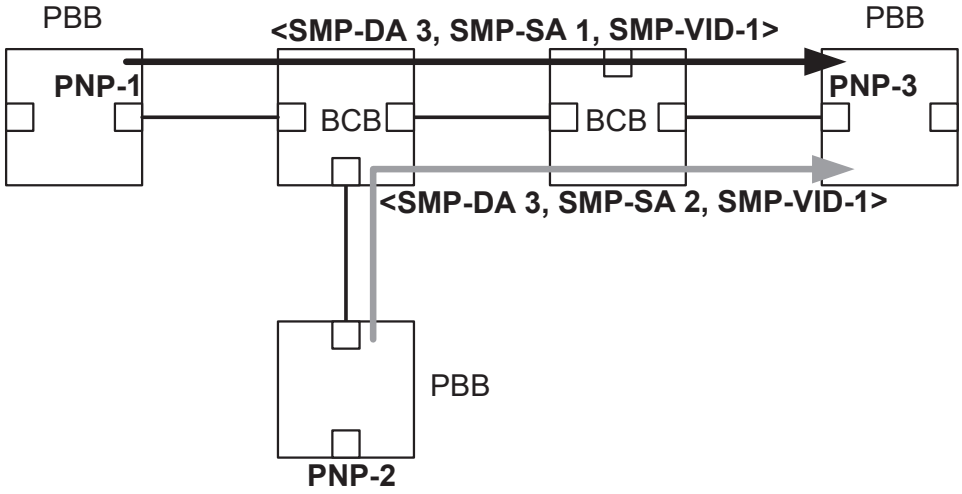

Figure 26-9—Independent Infrastructure Segments distinguished by SMP-SA

26.9.9 Infrastructure Segment MEP placement in a Bridge Port

Infrastructure Segment MEPs are always Down MEPs and are placed only on PNPs as these correspond to the demarcation points of the Infrastructure Segment. The Infrastructure Segment MEPs are placed between the Port filtering entities (8.6.1, 8.6.2, and 8.6.4) and the Queuing entities (8.6.5, 8.6.6, 8.6.7, and 8.6.8) in the SMP-VID space identified by the EISS Multiplex Entity (6.17). Since the Infrastructure Segment MAC addresses can be reused by different Infrastructure Segments, the Infrastructure Segment MEPs need to be further differentiated by the Infrastructure Segment Multiplex Entity (6.21). In principle, separately for each Infrastructure Segment, there can be from zero to eight Down MEPs, ordered by increasing MD Level, from Frame filtering towards Port filtering, even though not more than one MD Level is expected for Infrastructure Segment MAs. Figure 26-10 depicts an example of Infrastructure Segment MEPs on a PNP.

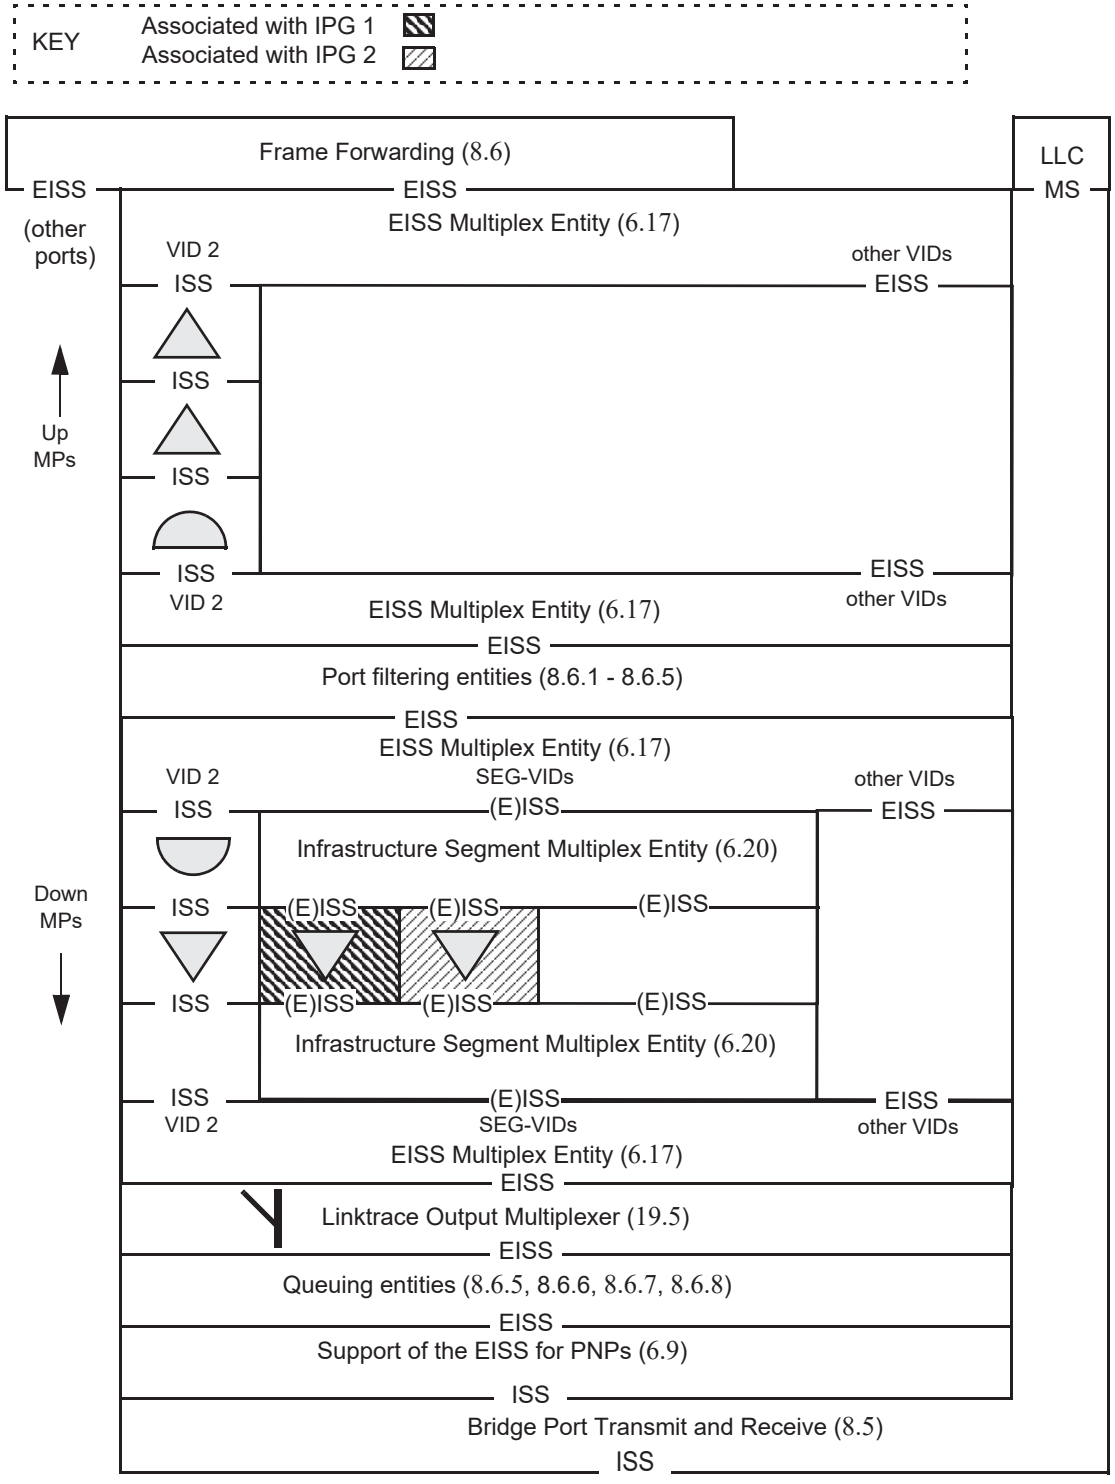

Figure 26-10—Infrastructure Segment MEP placement in a PNP

26.9.10 Infrastructure Segment Maintenance Domains

A PBB deploying IPS specifies a set of Infrastructure Segment MDs independent of those described in 26.8 and 26.9.5. In particular the CFM stacks in Figure 26-2 have Infrastructure Segment MD levels in parallel to the depicted Backbone MD levels for Ports instantiating Infrastructure Segments while Infrastructure Segment MDs will be present in parallel to the Backbone MD levels depicted in Figure 26-3.

26.9.11 IPS extensions to Continuity Check operation

The Continuity Check protocol is described in 20.1 and the corresponding state machines in Clause 20. The only enhancement required by the Infrastructure Segment MA is in the procedure that is responsible for constructing and transmitting a CCM (20.11.1):

a) The destination_address parameter is set to the MAC address indicated by the value of the SMP-DA field of the SMP-ID having as SMP-SA the MAC address of the MEP emitting the CCM.

All other Continuity Check processes are the same as those for a VID-based MA.

26.10 Protection switching for point-to-point TESIs

26.10.1 Introduction

In contrast to PBB, spanning tree protocols and broadcasting/flooding are not used in PBB-TE. FDBs are populated using a network management system or a control plane, allowing ESPs to be engineered and provisioned across the network. PBB-TE provides end-to-end linear protection for point-to-point TESIs, where a dedicated protection point-to-point TESI is established for one particular working point-to-point TESI, and the traffic is automatically switched from the working TESI to the protection TESI when a failure occurs on the working entity. The protection entity is preestablished, ensuring the availability of those resources when a defect is detected on the working entity, and allowing for a corresponding sub-50 ms switchover.

Figure 26-11 depicts the essential elements of the PBB-TE protection scheme and its arrangement. In this, 1:1 (i.e., 1 for 1) arrangement, traffic is sent on only one of the paths at any point in time based on information from OAM processes or network operators.

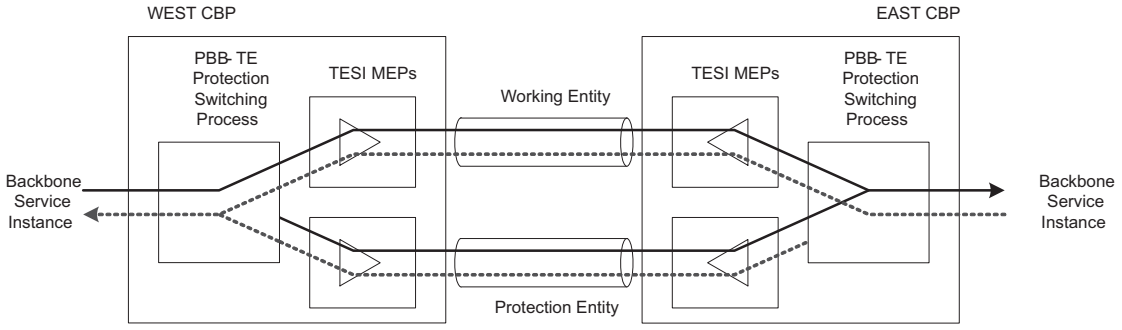

Figure 26-11—Protection switching architecture

Protection switching may be triggered by manual operation or by CFM information arising from, periodic monitoring of the working and protection paths, or from physical layer monitoring, such as loss of signal or other defects detected through CFM.

The PBB-TE protection switching mechanism aims to offer the capability to switch completely (both ends) in less than 50 ms following the detection of the fault.

NOTE 1—The capability of supporting the above switchover requirement on TESIs, is provided by configuring the interval of CCMs on the MAs associated these TESIs to be equal to or lower than 10 ms enabling the detection of the fault and the signaling of the coordination information end to end in less than 50 ms.

The PBB-TE protection scheme may be configurable to be "revertive" or "nonrevertive," where traffic transmission reverts, or not, to the working path automatically once CFM indicates the fault or defect has been cleared. The protection switching mechanism may also incorporate hold-off and wait to restore timers, the first to allow the fault to be protected by a lower layer protection switching mechanism for instance, while the latter ensures the performance of the working path is fully restored before switching back to it. The hold-off timer obviously slows the overall recovery time for a fault within the protected domain.

NOTE 2—A complete discussion on the various protection switching mechanisms and terminology is provided by ITU-T G.8031 [B48]. As a caution it should be noted that ITU-T uses the term "Bridge" for the logical entity that selects either or both of the transmit paths at the sending end of a protected domain. This is not to be confused with the term Bridge used in this standard.

The description herein, defines and provides a scalable end-to-end resiliency mechanism that offers end-to-end 1:1 bidirectional linear protection switching capable of load sharing for point-to-point TESIs in a PBB-TE Region.

NOTE 3—Some scenarios exist where multiple input events may cause the protection switching state machines in a protection group to select diverse TESIs on which to send traffic. The Mismatch defect informs the operator of such an occurrence thereby allowing the appropriate corrective action to be taken.

Protection for point-to-multipoint TESIs may be provided by external mechanisms or agents, which are out of scope for this specification.

26.10.2 1:1 point-to-point TESI protection switching

In a PBB-TE Region, IB-BEBs constitute the demarcation between the PBBN of interest and the networks attached to it. The protected domain is defined to be the area between the CBPs on the different B-Components of the involved IB-BEBs.

The starting point in providing protection switching is the creation and configuration of a TE protection group. A TE protection group is a group of two point-to-point TESIs between a pair of CBPs, which carries an assigned set of backbone service instances, and continues to carry these backbone service instances if any one of the TESIs in the group is failed or disabled. The creation of the TE protection group requires the assignment of one TESI as a working entity and a second TESI with the same terminating points as a protection entity providing a different bidirectional connectivity path (12.14.1.2). The configuration of the TE protection group is completed with the assignment of the list of the backbone service instances that are to be protected by the TE protection group [item b) in 12.18.2.1.3].

The protection switching mechanism is capable of load sharing as the TESIs that are assigned to a TE protection group can be reused in a number of TE protection groups enabling a list of I-SIDs to be distributed among a set of interdependent TE protection groups [item c) in 12.18.2.1.3]. A set of interdependent TE protection groups forms a coordinated protection group. Protection switching requests to interdependent TE protection groups must be coordinated for an operator to manage the TESIs in a coherent manner and to avoid potentially competing requests for each TESI. For example, to unconditionally remove traffic from a TESI, one request to Lock Out the TESI results in a request to each TE protection group to which the TESI belongs, either LoP or FS according the role of the TESI in each group. Similarly, to conditionally remove traffic from a TESI, one Manual Switch request for the TESI results in the appropriate Manual Switch request to each TE protection group to which the TESI belongs. Allowing a single operator request per coordinated protection group and coordinating the resulting requests to each TE protection group reduces the operational complexity of the set of interrelated TE protection groups. Using a coordinated

protection group, the service traffic (backbone service instance) load can be shared across a set of TESIs and at the same time be protected against single faults by 1:1 protection.

NOTE 1—If the operator initiates switching of an individual load shared TE protection group the mmCCMdefect may not detect a switch mismatch.

NOTE 2—The load sharing mode of operation corresponds to 1:1 ETH Sub Network Connection Group protection with Inherent monitoring (ETH SNCG/I) in the ITU-T protection switching terminology.

The following description of the PBB-TE protection switching mechanism is an example provided for illustrative purposes. Figure 26-12 depicts a network where two point-to-point TESIs have been provisioned. The TE-1 service instance on the top of the figure consists of two ESPs each identified by a 3-tuple: <CBP-B, CBP-A, VID-1> is depicted in black and <CBP-A, CBP-B, VID-2> in gray. The TE-2 service instance below consists of two other ESPs identified by the 3-tuples <CBP-B, CBP-A, VID-3> and <CBP-A, CBP-B, VID-3> which are depicted in white. The use of the same ESP-VID on the TE-2 ESPs is only for illustrative purposes. There are no explicit requirements on using the same or different ESP-VIDs on the ESPs comprising the TESIs that are assigned to a TE protection group. One set of backbone service instances, shown by the black arrows just outside the two CBPs, has TE-1 assigned as its working TESI and TE-2 assigned as its protecting TESI.

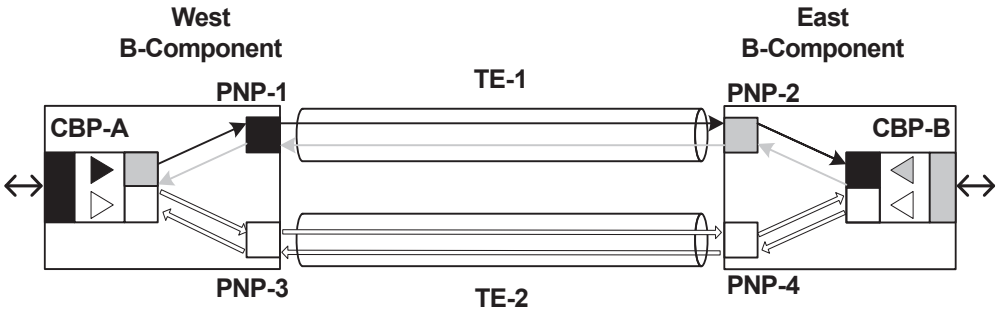

Figure 26-12—PBB-TE point-to-point protection switching

The ESPs are provided by configuring entries in the FDBs on all the Bridges that these ESPs need to pass through. On the terminating IB-BEBs, the VLAN membership of each participating port has to be configured for the B-components. In Figure 26-12, this is depicted by the color of the boxes that are placed inside each of the B-Component boxes. For example, the upper right PNP-1 port on the West B-component is a member of the VID-1 (black), while the CBP on the same component is a member of VID-2 (gray) and VID-3 (white). Only frames tagged with the appropriate VID parameter can egress these ports.

NOTE 3—The PNPs are shown for illustrative purposes only and that there is no explicit requirement to diversify PNPs on the terminating IB-BEBs.

Each of the TESIs is monitored by an independent MA. One MA is set to monitor the top (TE-1) TESI and a second to monitor the bottom (TE-2) TESI. Each of these two MAs is associated with a pair of ESPs and identified by their corresponding 3-tuples. Two Up MEPs, associated with the MA monitoring the TE-1 service instance, are configured on the CBPs that terminate the TE-1 service instance. Each of these MEPs has its own primary VID, VID-1 (black) for the MEP on the West B-component associated with the TE-1 service instance, and VID-2 (gray) for the MEP on the East B-component. In this configuration each MEP receives frames that are tagged with the ESP-VID corresponding to the primary VID of the associated remote MEP and can only send frames that are tagged with its own primary VID. In particular, in the depicted example the MEP for the top entity on the West B-component can send only CCMs tagged with VID-1 (black) and receive CCMs tagged with VID-2 (gray), while the corresponding MEP on the East component can only send CCMs tagged with VID-2 (gray) and receive CCMs tagged with VID-1 (black). The primary VID of each MEP is depicted by the color of the MEP. It should be also noted that all the depicted ports in Figure 26-12 have their Enable Ingress Filtering parameter (8.6.2) reset to its default value, i.e., Disable Ingress Filtering.

Data traffic is mapped to a TESI by configuring the CBP parameters (6.11). In particular, the CBP I-SID is used to allow specific service instances to be carried by the TESI while the entries of the B-VID column in the Backbone Service Instance table are indicating how to map the identified service instances to a specific ESP. The CBP's B-VID value is depicted in Figure 26-12 by the color of the vertical bars (black for CBP-A, gray for CBP-B) placed at the tips of the arrows representing the set of backbone service instances.

As a result customer frames that need to be transported by a TESI and are identified by a specific I-SID and reach the CBP on the West B-component from the left can be mapped to the black ESP or the white ESP while frames on the same service that reach the CBP on the East B-component from the right will be mapped to the gray ESP or the white ESP based on the CBP's configured B-VID value. If all the services are normally mapped to the black ESP and gray ESP, then TE-1 would correspond to the working entity and TE-2 to a stand-by protection entity. Irrespective of how the data traffic is mapped to the TESIs, CCM frames are exchanged on both TESIs in order to regularly check the provided connectivity.

If a fault occurs on any of the ESPs, the MEP on the receiving end will be notified. In particular if a fault on the black ESP occurs, as shown in Figure 26-13, the MEP on the East B-component will declare a remote MEP defect by setting the rMEPCCMdefect parameter (20.19.1). The timer counter for timing out CCMs has a granularity finer than or equal to 1/4 of the time represented by the CCMinterval variable (20.8.1). A Bridge does not set rMEPCCMdefect within (3.25 × CCMinterval) seconds of the receipt of a CCM, and sets rMEPCCMdefect within (3.5 × CCMinterval) seconds after the receipt of the last CCM. The setting of the rMEPCCMdefect parameter will result in a change of the appropriate B-VID entries in the Backbone Service Instance table, of the east CBP from the gray VID-2 to the white VID-3, which is the ESP-VID of the associated ESP on the protection TESI.

NOTE 4—The B-VID parameter will also change when the xConCCMdefect (20.23.3) or the errorCCMdefect (20.21.3) parameters are set as these indicate a very serious misconfiguration problem.

All subsequent CCMs sent by the east gray MEP on TE-1 will have the RDI field set for as long as proper CCMs are not received by the MEP. A reception of a CCM frame with the RDI field set (or an event that causes setting of the someRMEPCCMdefect, xConCCMdefect, or errorCCMdefect) by the MEP associated with TE-1 on CBP-A will cause a change of the appropriate B-VID entries in the Backbone Service Instance table of the CBP-A on the West B-component, to the pre-configured value of the protection ESP. The result will be to move the affected service instances to the protection TE-2 service instance as depicted Figure 26-13. Consequently, the approximate maximum time before a bidirectional switch occurs following a unidirectional failure would be approximately equal to (3.5 × CCMinterval) + the time required for a CCM PDU to travel between the MEPs monitoring the TESI + the time to update the associated Backbone Service Instance table entries.

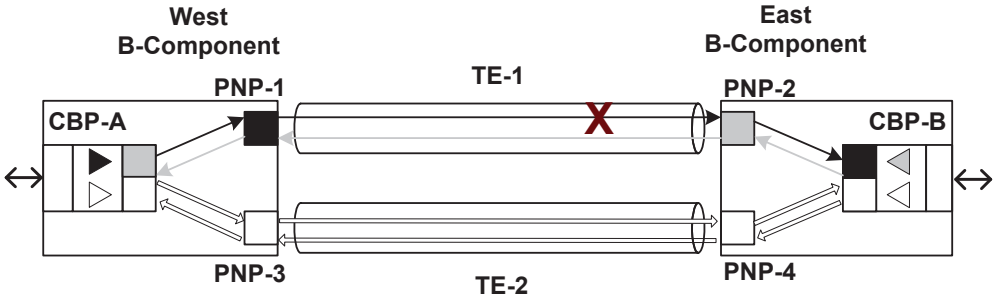

Figure 26-13—Mapping data traffic to the protection entity

26.10.3 Protection Switching state machines

The local protection commands and protection behavior specified here follow the architectural model used in ITU-T G.8031 [B48]. The relationships among the protection switching state machines are illustrated in Figure 26-14. That figure uses conventions similar to those of 13.24, and of Figure 13-13: open arrows denote variables that are set by one state machine and both read and set by another; closed arrows denote variables that are set by the owning state machine, and only read by other state machines.

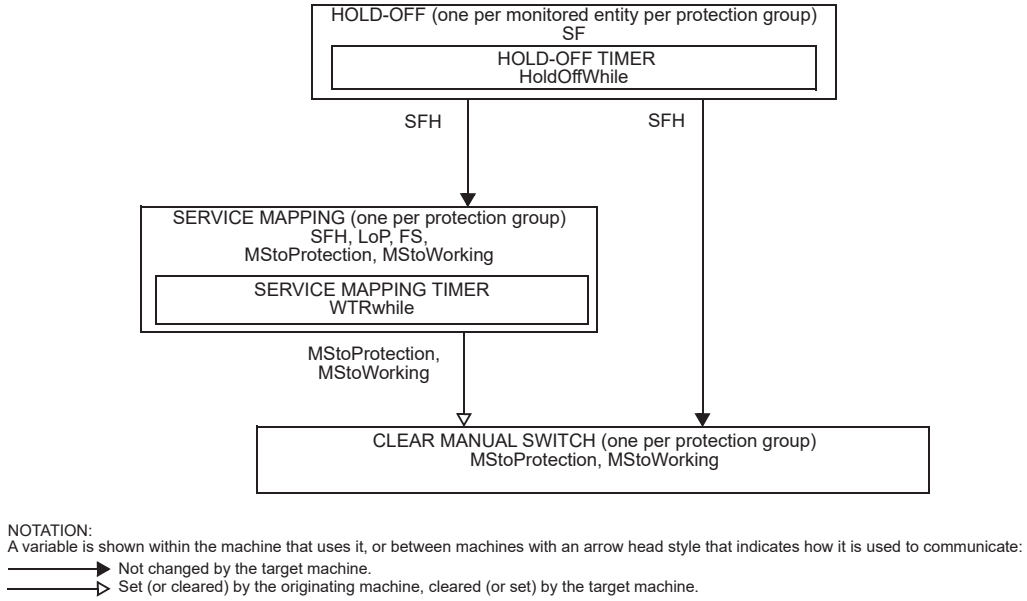

Figure 26-14—Relationships of the Protection switching state machines—overview

There is one set of Protection Switching state machines per protection group on each Bridge that terminates the protection group. The protection group consists of the working and the protection entities. The Protection Switching state machine reuses the defect variables that are presented in Table 20-1. Variables and procedures that are preceded with "w." refer to the working entity while those that are preceded with "p." refer to the protection entity. These internal prefix/entity associations remain the same following a protection switch to the protection entity.

26.10.3.1 Notational conventions used in state diagrams

The Protection Switching state machines are specified using the notational conventions defined in Annex E.

26.10.3.2 State machine timers

The timer variables declared in this subclause are part of the specification of the operation of Protection Switching. The accompanying descriptions of their meaning and use are provided to aid in the comprehension of the protocol only, and are not part of the specification.

One instance of the following may be implemented per Service Mapping state machine:

a) WTRwhile (26.10.3.2.1)

One instance of the following may be implemented per Hold-off state machine:

b) HoldOffWhile (26.10.3.2.2)

26.10.3.2.1 WTRwhile

A timer to be used to prevent frequent operation of the protection switch due to an intermittent defect. This timer allows for a fixed period of time to elapse before data traffic is mapped from the protection entity to the working entity when in revertive mode.

26.10.3.2.2 HoldOffWhile

In order to coordinate timing of protection switches at multiple layers or across cascaded protected domains, a hold-off timer may be required. The purpose is either to allow a server layer protection switch to have a chance to fix the problem before switching at a client layer, to allow an upstream protected domain to switch before a downstream domain, or to allow the inner protected domain to switch before the outer protected domain in the case of IPS nested protection domains.

26.10.3.3 Protection Switching variables

The following variables are defined for the Protection Switching state machines:

a) BEGIN (26.10.3.3.1)
b) SF (26.10.3.3.2)
c) SFH (26.10.3.3.3)
d) LoP (26.10.3.3.4)
e) FS (26.10.3.3.5)
f) MStoProtection (26.10.3.3.6)
g) MStoWorking (26.10.3.3.7)
h) WTRTime (26.10.3.3.8)
i) HoldOffTime (26.10.3.3.9)

Table 26-2 illustrates the inherent priority of each protection request.

Table 26-2—Protection Requests Hierarchy

Priority	Request
highest	LoP
	FS
	p.SF
	w.SF
	MStoProtection, MStoWorking
	WTR
lowest	NoRequest

NOTE—The priorities associated with the various requests in this table are in general alignment with the corresponding priorities in ITU-T G.8031 [B48]. The only difference is that the precedence of p.SF and FS are inverted since ITU-T G.8031 relies on an APS protocol to be running on the protection path.

26.10.3.3.1 BEGIN

This is a Boolean variable controlled by the system initialization process. A value of TRUE causes all Protection Switching state machines per protection group to continuously execute their initial state. A value of FALSE allows these state machines to perform transitions out of their initial state, in accordance with the relevant state machine definitions.

26.10.3.3.2 SF

SF is the logical OR of someRMEPCCMdefect (20.35.5), someRDIdefect (20.35.7), xConCCMdefect (20.23.3), and errorCCMdefect (20.21.3).

NOTE—Locally detected MAC/PHY faults may also be components of SF (e.g., to enable potentially faster fault detection), but are outside the scope of this standard.

26.10.3.3.3 SFH

A Boolean flag set and cleared by the Hold-off state machine to indicate that SF is set for a period that is equal to, or larger than, the HoldOffTime. The variable will be set equal to SF if the Hold-Off timer is not supported.

26.10.3.3.4 LoP

A Boolean flag indicating the administrative state of the protection entity. If set, it prohibits the use of the protection entity. Its value can only be controlled by an administrator action [item b2) in 12.18.2.3.2].

26.10.3.3.5 FS

A Boolean flag indicating the presence of an administrative command to force switch the data traffic to the protection entity. Its value is set to 1 by an administrator action [item b3) in 12.18.2.3.2 or 12.24.2.3.2]. It can be reset by an administrator action that corresponds to a request of the same or higher priority according to Table 26-2.

26.10.3.3.6 MStoProtection

A Boolean flag indicating the presence of an administrative command to manually switch the data traffic to the protection entity, in the absence of a failure of the working or the protection entity. Its value is set to 1 by an administrator action [item b4) in 12.18.2.3.2 or 12.24.2.3.2]. It can be reset by an administrator action that corresponds to a request of the same or higher priority according to Table 26-2 and by the operation of the Clear Manual Switch state machine.

26.10.3.3.7 MStoWorking

A Boolean flag indicating the presence of an administrative command to manually switch the data traffic to the working entity in the absence of a failure of the working or the protection entity. Its value is set to 1 by an administrator action [item b5) in 12.18.2.3.2 or 12.24.2.3.2]. It can be reset by an administrator action that corresponds to a request of the same or higher priority according to Table 26-2 and by the operation of the Clear Manual Switch state machine.

26.10.3.3.8 WTRTime

The wait-to-restore (WTR) period, as provided by the corresponding managed object item e) in 12.18.2.1.3 or item h) in 12.24.2.1.3]. May be configured by the operator in 1 min steps between 5 and 12 min; the default value is 5 min. A value of 0 indicates nonrevertive mode. The overall accuracy of the WTR timer (e.g., < ±25 ms) should be sufficient to allow both ports at the protection domain termination to revert to the working entity in less than 50 ms.

26.10.3.3.9 HoldOffTime

The Hold-Off period as provided by the corresponding managed object [item f) in 12.14.6.1.3 or item i) in 12.24.2.1.3]. The suggested range of the hold-off timer is 0 to 10 s in steps of 100 ms (accuracy of ±5 ms); the default value is 0.

26.10.3.4 Protection Switching procedures for PBB-TE TESI Protection

The following procedures are defined for the Service Mapping state machine:

a) mapDataToWorking() (26.10.3.4.1)
b) mapDataToProtection() (26.10.3.4.2)

NOTE 1—Since a merging selector is used, there is the potential for misordered frames at egress due to differential delay between the working and protection TESIs following a protection switch. If this is a concern, then briefly discarding frames prior to executing either mapDataToX() processes described in 26.10.3.4.1 or 26.10.3.4.2 will avoid the issue (e.g., 1 ms is equivalent to a 20% differential delay across 1000 km of fiber).

NOTE 2—The procedure descriptions in this subclause are specific to PBB-TE TESI Protection. A description of the corresponding procedures for IPS can be found in 26.11.4.1.1 and 26.11.4.1.2.

26.10.3.4.1 mapDataToWorking()

Maps the customer service(s) that are to be transported by a TE protection group [item b) in 12.18.2.1.3], to the working TESI identified by the 3-tuples <remote CBP MAC, local CBP MAC, ESP-VID(w)>, <local CBP MAC, remote CBP MAC, ESP-VID(w')>, by setting the VID values of the corresponding I-SID entry(-ies) in the Backbone Service Instance table to the ESP-VID(w).

26.10.3.4.2 mapDataToProtection()

Maps the customer service(s) that are to be transported by a TE protection group [item b) in 12.18.2.1.3], to the protection TESI identified by the 3-tuples <remote CBP MAC, local CBP MAC, ESP-VID(p)>, <local CBP MAC, remote CBP MAC, ESP-VID(p')>, by setting the VID values of the corresponding I-SID entry(ies) in the Backbone Service Instance table to the ESP-VID(p).

26.10.3.5 Protection Switching state machine diagram

The Protection Switching state machines implement the function specified by the state diagrams in Figure 26-15, Figure 26-16, and Figure 26-17, the variables in 26.10.3.3, and the procedures in 26.10.3.4. The Hold-off state machine shall be present only when the Hold-off timer is supported.

The current state of the Service Mapping state machine is available as a managed object [item c) in 12.18.2.1.3].

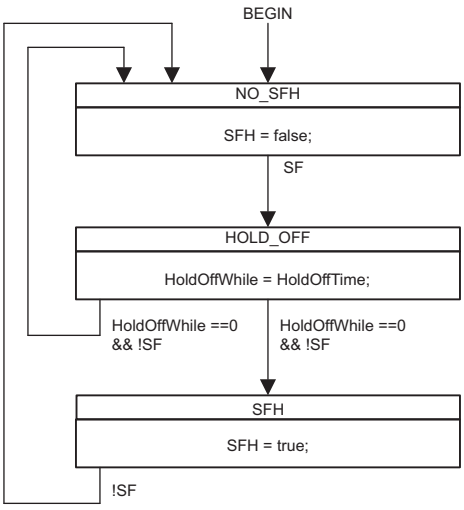

Figure 26-15—Hold-off state machine

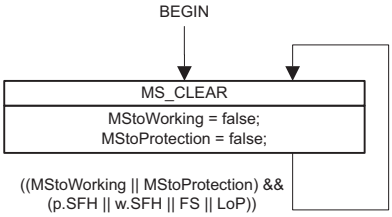

Figure 26-16—Clear Manual Switch state machine

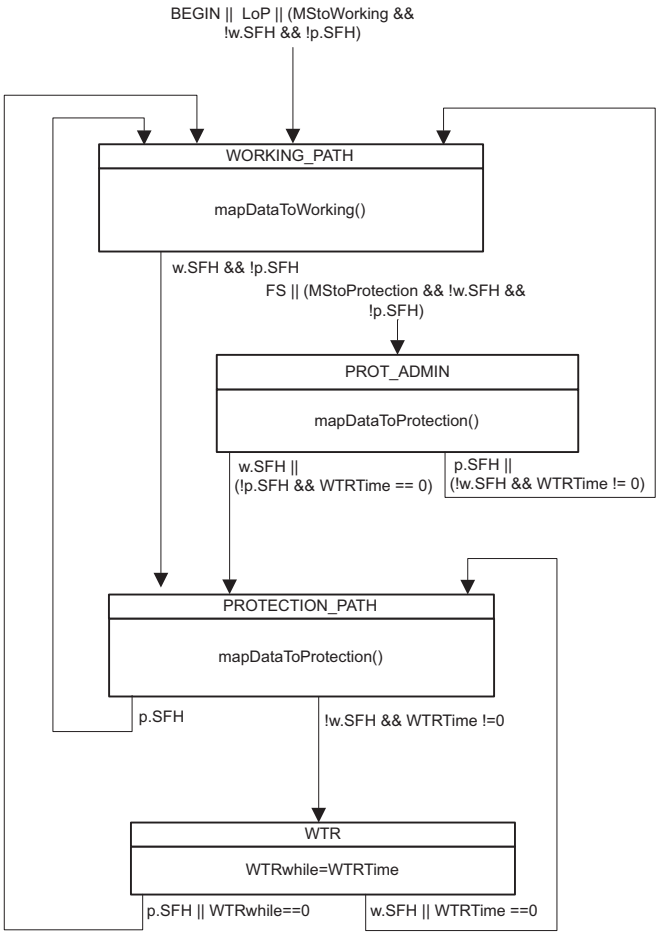

Figure 26-17—Service Mapping state machine

26.11 IPS in PBB-TE Region

In addition to supporting end-to-end linear protection for TESIs (26.10), PBB-TE supports localized protection of selected TESIs traversing a common sequence of PNPs. Such a sequence of PNPs, together with the intervening MAC relay entities and LANs, is called an Infrastructure Segment. The group of TESIs associated with the Infrastructure Segment is protected from the failure of one or more components (i.e., port, LAN, or MAC Relay Entity) of the Infrastructure Segment. The method of providing such protection is called Infrastructure Protection Switching (IPS). 1:1 IPS and M:1 IPS are described by this standard. Support for IPS is optional. If IPS is supported, 1:1 IPS is required, and M:1 IPS is optional. IPS may be triggered automatically by a change in the operational state of an Infrastructure Segment or manually by administrative command.

NOTE—A complete discussion on the various protection switching mechanisms and terminology is provided by ITU-T G.8031 [B48]. The ITU-T uses the term “bridge” for the logical entity that selects either or both of the transmit paths at the sending end of a protected domain. This is not to be confused with the term “Bridge” used in this standard.

As illustrated in Figure 26-18, a Bridge supporting IPS is a PBB. Definitions of entities associated with an Infrastructure Segment and properties of such entities are as follows:

a) A PBB terminating the Infrastructure Segment is a Segment Endpoint Bridge (SEB).
b) A PBB in the interior of the Infrastructure Segment is a Segment Intermediate Bridge (SIB).
c) A PNP terminating the Infrastructure Segment is called a Segment Endpoint Port (SEP).
d) A PNP in the interior of the Infrastructure Segment is called a Segment Intermediate Port (SIP).
e) A SEB contains one SEP and does not contain a SIP.
f) A SIB contains exactly two SIPs and, by definition, cannot contain a SEP.
g) A SEP is connected to a single SIP or SEP in a neighboring PBB via a LAN.
h) A SIP is connected to one other SIP within the SIB via the MAC Relay Entity and is connected to a single SEP or SIP in a neighboring PBB via a LAN.

The role of SEB or SIB is assigned to a PBB only with respect to a particular Infrastructure Segment. Similarly, the role of SEP or SIP is assigned to a Port only with respect to a particular Infrastructure Segment.

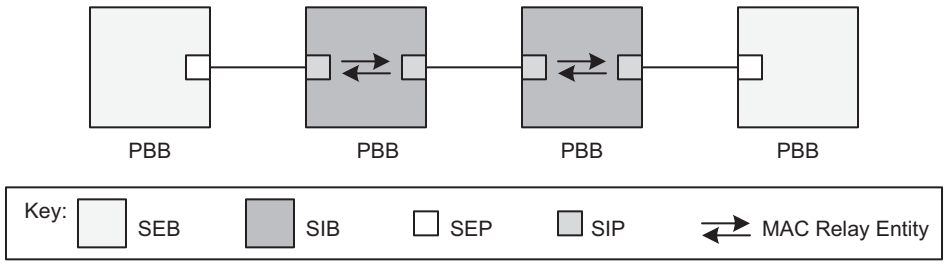

Figure 26-18—Segment terminology and properties

26.11.1 Infrastructure Segment monitoring

As illustrated in Figure 26-19, each Infrastructure Segment is associated with an MA for purposes of determining the connectivity state of that Infrastructure Segment. The Infrastructure Segment MA is associated with a pair of co-routed counterdirectional Infrastructure Segment Monitoring Paths (SMPs). Each SMP is identified by an <SMP-DA, SMP-SA, SMP-VID> 3-tuple that is known as an SMP-ID. The SMP-SA takes the value of the MAC address of the SEP from which the SMP originates. The SMP-DA takes the value of the MAC address of the SEP in which the SMP terminates. It follows from the co-routed and counterdirectional properties of the pair of SMPs that the SMP-DA value of one SMP in the pair of SMPs is equal to the SMP-SA value of the other SMP of the pair. The SMP-VID is a VID associated with a special value of the Multiple Spanning Tree Instance Identifier (MSTID) in the MST Configuration Table, the TE-MSTID, indicating that the VID is under the control of an external agent (8.9). The pair of SMP-IDs associated with an Infrastructure Segment is known as an Infrastructure Segment Identifier (SEG-ID). The MA managed object (12.14.6) associated with an Infrastructure Segment specifies the SEG-ID identifying that Infrastructure Segment. The value of the SEG-ID is inherited by the MEP associated with the Infrastructure Segment MA.

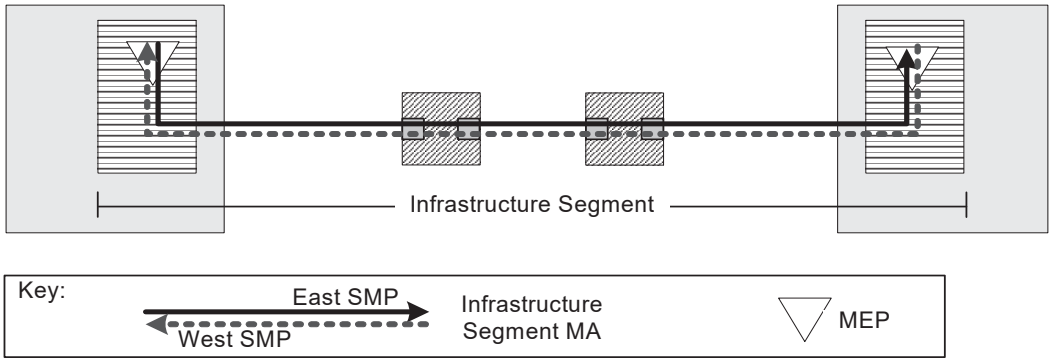

Figure 26-19—Infrastructure Segment monitoring

The operational state of the Infrastructure Segment is indicated by the Signal Fail (SF) variable (26.10.3.3.2) of the Protection Switching state machines (26.10.3). A value of TRUE indicates that the associated Infrastructure Segment is not operational. A value of FALSE indicates that the associated Infrastructure Segment is operational.

NOTE—For proper network operation, each SMP, of the pair of SMPs identifying an Infrastructure Segment MA, is represented by a Static Filtering Entry configured via the Create Filtering Entry operation (12.7.7.1) in each SIB along the path of the Infrastructure Segment. The SMP-ID <SMP-DA, SMP-SA, SMP-VID> would be represented by the Static Filtering Entry <SMP-DA, SMP-VID, outbound port value>. The outbound port value is the port number of the port by which the SMP exits the SIB. Proper operation further includes the creation, at each SEP, of a Maintenance Domain managed object (12.14.5), a Maintenance Association managed object (12.14.6), and a Maintenance association Endpoint managed object (12.14.7) associated with the Infrastructure Segment MA.

26.11.2 1:1 IPS

Figure 26-20 depicts two Infrastructure Segments with a TESI that has been provisioned to fully traverse the upper Infrastructure Segment. The Infrastructure Segment traversed by the provisioned TESI is known as the Working Segment with respect to that TESI. The lower Infrastructure Segment terminates in the same pair of SEBs that terminates the Working Segment but is otherwise diverse from the Working Segment. The lower Infrastructure Segment is known as the Protection Segment with respect to the TESI that traverses the Working Segment.

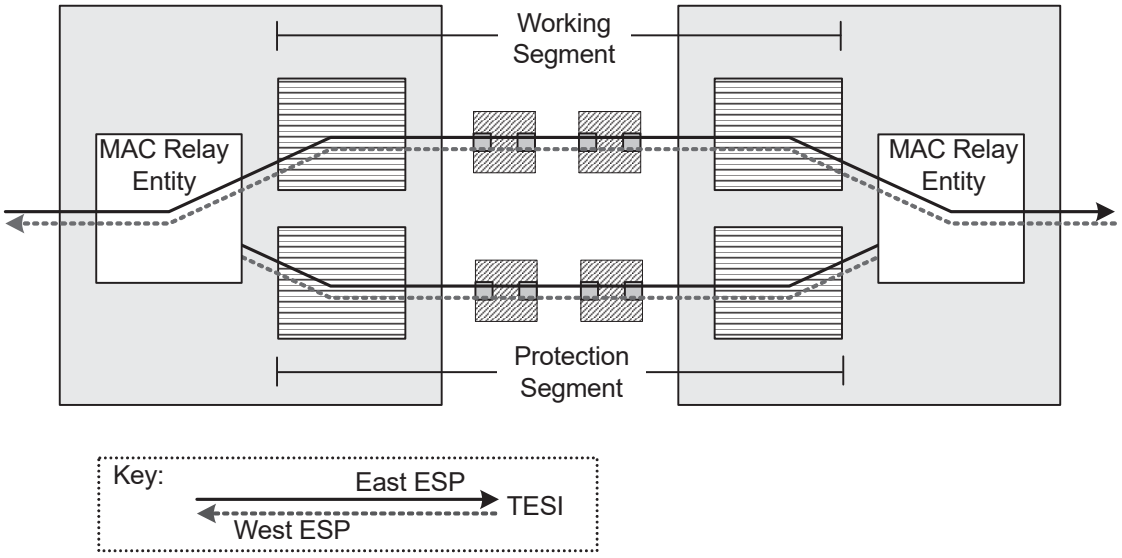

Figure 26-20—Working Segment and Protection Segment

26.11.2.1 Infrastructure Protection Group (IPG)

The associated Working and Protection Segments depicted in Figure 26-20 are said to form an IPG. The Working and Protection Segments are fully disjoint except for the common SEBs in which they terminate; that is, they share no common SEP, SIB, SIP, LAN, or MAC Relay Entity. One or more TESIs, each identified by a TE-SID are associated with an IPG at the SEB by which the TESI enters that IPG. A TESI is associated with the IPG via the Write IPG managed object (12.24.2.2.) Multiple TESIs may be associated with an IPG. TESIs associated with an IPG may have diverse end-to-end paths, but they follow a common path traversing the IPG. Two or more TESIs may be associated with ESPs having the same <ESP-DA, ESP-VID> 2-tuple. In particular this can occur if the TESIs are distinguished only by different values of ESP-SA. In such cases where TESIs share a common value of <ESP-DA, ESP-VID>, the association of one such TESI with an IPG at a SEB implies that all such TESIs are associated with that IPG. In other words, all such TESIs are protected by the IPG, or no such TESIs are protected by the IPG.

NOTE—An Infrastructure Segment can be associated with more than one IPG. For example, the operator can designate Infrastructure Segment 1 as the Working Segment of IPG1 and Infrastructure Segment 2 as the Protection Segment of IPG1. The operator can concurrently designate Infrastructure Segment 2 as the Working Segment of IPG2 and Infrastructure Segment 1 as an Protection Segment of IPG2. This property can be utilized as a method of load sharing across multiple Infrastructure Segments during normal operation.

26.11.2.1.1 Nested IPGs

IPGs are said to be nested with respect to a TESI if:

a) The TESI is associated with both IPGs, and
b) The set of SEPs and SIPs comprising the Working Segment of one IPG, the inner IPG, is identical to a contiguous sequence of SIPs contained within the Working Segment of the other IPG, the outer IPG.

In Figure 26-21, IPG2 (dashed) is nested within IPG1 (solid). IPG1 is the outer IPG, and IPG2 is the inner IPG. The Working Segment of the inner IPG is fully contained within the Working Segment of the outer IPG. The SEBs associated with the outer IPG are different from those associated with the inner IPG. Each nested IPG deploys an independent set of MAs for the purpose of monitoring the operational state of Infrastructure Segments associated with that IPG.

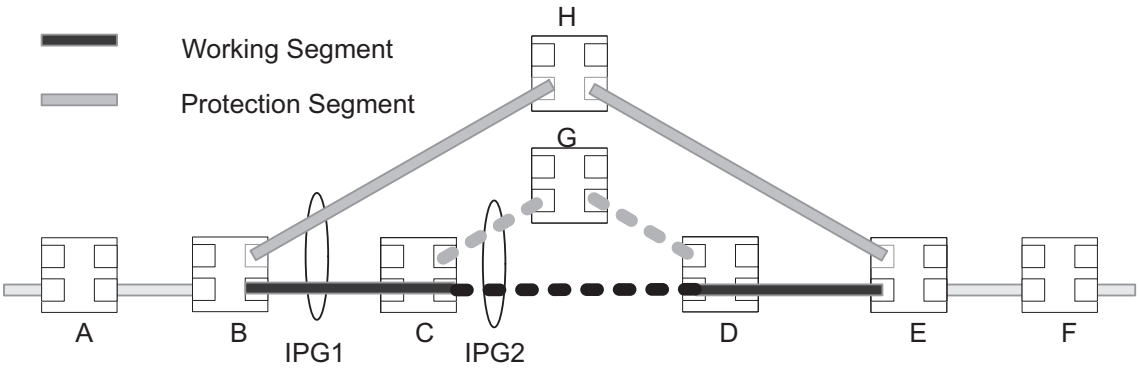

Figure 26-21—Nested IPGs

NOTE—Two IPGs are said to overlap with respect to a TESI if (a) the TESI is associated with both IPGs and (b) the IPGs share a sequence of PNPs. Designing networks having IPGs that overlap, but are not nested, requires careful study of issues not specifically identified in this standard.

26.11.2.2 Protection Switching method

When a TESI is assigned to an IPG by provisioning, traffic associated with that TESI transits the IPG via the Working Segment or the Protection Segment as directed by the Protection Switching state machines (26.10.3). In the absence of faults or outstanding administrative commands, TESI traffic transits the IPG via the Working Segment. The Protection Switching state machines can cause the TESI traffic to transit the IPG via the Protection Segment by invoking the Protection Switching procedure mapDataToProtection() (26.11.4.1.2). This procedure causes the value of the outbound Port field of the FDB entry corresponding to the <ESP_{in}-DA, ESP_{in}-VID> 2-tuple of each TESI associated with the IPG to be assigned the Port Number associated with the Protection Segment. The notation "ESP_{in}" denotes the ESP, of the pair of ESPs associated with the TESI, that *enters* the IPG via the SEB. The Protection Switching state machines can cause the traffic to transit the IPG via the Working Segment by invoking the Protection Switching procedure mapDataToWorking() (26.11.4.1.1) (26.11.4.1.2). This procedure causes the value of the outbound Port field of the FDB entry corresponding to each <ESP_{in}-DA, ESP_{in}-VID> 2-tuple of each TESI associated with the IPG to be assigned the Port Number associated with Working Segment. The two SEBs associated with the IPG perform protection activities independently. At any point in time, traffic associated with an IPG is carried on either the Working Segment or the Protection Segment. The Infrastructure Segment carrying the TESI traffic is known as the active Infrastructure Segment.

NOTE—Proper operation of the network requires that the FDB entry provisioned in a SIB to forward traffic along an Infrastructure Segment associated with the IPG identify only a single outbound Port. In other words, the portion of a TESI transiting an IPG is provisioned as point-to-point, without regard to whether the TESI is point-to-point or point-to-multipoint from an end-to-end perspective.

26.11.2.3 Hold-off timer

An IPG is provisioned with a "hold-off timer" value. The hold-off timer delays protection action associated with the failure of an Infrastructure Segment. The delay provides a lower layer with the opportunity to take corrective action before IPS is performed. Use of the hold-off timer can increase the total time required to recover from a failure.

In the case of nested IPGs, proper operation of the network requires that the outer IPG be provisioned with a "hold-off timer" value greater than that of the inner IPG. The outer IPG Working Segment is provisioned to coincide with the path of the inner IPG Working Segment. CCM traffic monitoring the outer IPG Working Segment traverses the Active Segment of the Inner IPG. The TESI list associated with the Inner IPG Endpoint Bridge is provisioned to include the SEG-ID associated with the CCM on the outer IPG Working Segment MA that ingresses the Inner IPG SEB. Thus, on a failure of the inner IPG Working Segment, traffic

associated with the outer IPG Working Segment, including the CCM traffic associated with the outer IPG Working Segment MA, is protected. The outer IPG will not be aware of the protection switch of the inner IPG and will not perform protection switching activities.

26.11.2.4 Reversion

An IPG is provisioned to operate in revertive mode or nonrevertive mode. In revertive mode, traffic is switched from the Protection Segment to the Working Segment when the Working Segment becomes operational. In nonrevertive mode, traffic remains associated with the Protection Segment when the Working Segment becomes operational unless:

a) The Protection Segment fails, or
b) Traffic is switched to the Working Segment by administrative command.

An IPG operates in revertive mode if that IPG is provisioned to support M:1 IPS.

26.11.2.4.1 Wait-to-restore timer

An IPG operating in revertive mode is provisioned with a "wait-to-restore (WTR) timer" value. The WTR timer delays reversion from the Protection Segment to the Working Segment on recovery of the Working Segment. Use of the WTR timer reduces the severity of "flapping," or rapid oscillation, that may occur if the Working Segment is experiencing intermittent connectivity failure. Setting the WTR time to zero indicates that the IPG is operating in nonrevertive mode.

26.11.2.5 Administrative commands

IPS supports the following administrative commands:

— **Lockout of Protection (LoP)** allows the operator to suppress automatic switching from Working Segment to Protection Segment.
— **Forced Switch (FS)** allows the operator to force traffic to the Protection Segment as if a connectivity failure exists on the Working Segment. The behavior persists until the command is withdrawn.
— **Manual Switch to Protection (MStoProtection)** switches traffic to the Protection Segment, but does not force traffic to remain associated with the Protection Segment.
— **Manual Switch to Working (MStoWorking)** switches traffic to the Working Segment, but does not force traffic to remain associated with the Working Segment.

26.11.3 IPS Control entity

The IPS Control entity contains the 1:1 IPS state machines (26.11.4) and, if M:1 IPS (26.11.5) is supported, the M:1 IPS state machines (26.11.5.1). There is an instance of the IPS Control entity for each SEB.

As shown in Figure 26-22, the operation of the IPS state machines depends upon input from Bridge Management and from each Infrastructure Segment MA associated with the IPG. The input from Bridge Management includes the list of TESIs [item e) in 12.14.2.1.2] associated with the IPG and Administrative commands (26.11.2.5) associated with the IPG. The outbound Port field of a Static Filtering Entry associated with an IPG can be modified by IPS Control. When a Static Filtering Entry is no longer associated with an IPG, the Outbound Port value of that Static Filtering Entry is restored by IPS control to the Port associated with the Working Segment of the IPG and IPS Control cannot subsequently modify the Outbound Port value. While the Outbound Port value can be modified by IPS Control, addition and deletion of FDB entries remains under the control of Bridge Management.

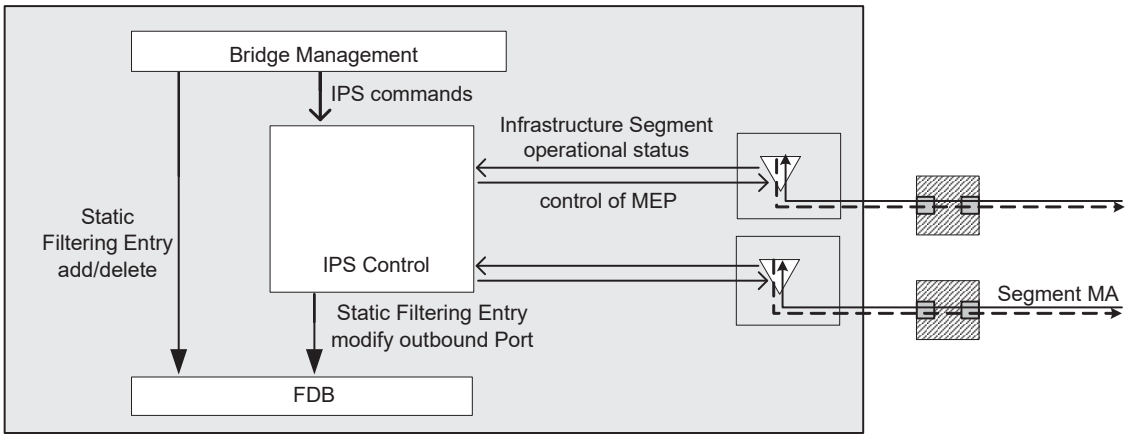

Figure 26-22—IPS Control entity

IPS Control maintains the following entities associated with the IPG:

a) The SEG-ID identifying the Working Segment MA
b) The SEG-ID identifying the Protection Segment MA
c) The 1:1 IPS state machines
d) The list of the TESIs describing traffic protected by the IPG

When an IPG is associated with optional M:1 IPS, the following additional entities are maintained:

e) The list of SEG-IDs identifying the MAs of candidate Protection Segments
f) The M:1 IPS state machines

26.11.4 1:1 IPS state machines

Protection switching for point-to-point TESIs (26.10) and 1:1 IPS (26.11.2)both utilize Protection Switching state machines (26.10.3). In the case of 1:1 IPS, the “Protection Group” is an “IPG,” the “working entity” is the “Working Segment,” and the “protection entity” is the “Protection Segment.” One set of Protection Switching state machines is instantiated per IPG per SEB.

26.11.4.1 Procedures referenced by the 1:1 IPS state machines

The procedures mapDataToWorking() and mapDataToProtection() referenced by the 1:1 IPS state machines and described in the subclauses that follow, differ from the procedures of the same name (26.10.3.4) referenced by the TESI Protection state machines.

26.11.4.1.1 mapDataToWorking()

This procedure changes the value of the outbound Port field of each Static Filtering Entry identified by the <ESP_{in}-DA, ESP_{in}-VID> 2-tuple associated with each TESI on the list of TESIs associated with an IPG to the port Number associated with the Working Segment of the IPG.

26.11.4.1.2 mapDataToProtection()

This procedure changes the value of the outbound Port field of each Static Filtering Entry identified by the <ESP_{in}-DA, ESP_{in}-VID> 2-tuple associated with each TESI on the list of TESIs associated with an IPG to the port Number associated with the Protection Segment of the IPG.

26.11.5 M:1 IPS

This subclause describes extensions to 1:1 IPS (26.11.2) supporting M:1 IPS when this optional feature is implemented. An IPG is constrained to operate in 1:1 revertive mode when that IPG supports M:1 IPS.

As illustrated in Figure 26-23, a list of candidate Protection Segments, ordered by priority value, is provisioned for each IPG. deploying M:1 IPS. The list contains at least one candidate Protection Segment. Candidate Protection Segments are mutually disjoint and disjoint from the Working Segment. The candidate Protection Segment having the highest (lowest numeric) priority among the operational candidate Protection Segments is the Protection Segment referenced by the 1:1 IPS state machine. This selected candidate Protection Segment is called the “current” Protection Segment. In the absence of any operational candidate Protection Segments, the current Protection Segment retains the value it had prior to the failure of the last candidate Protection Segment. In this case, the 1:1 IPS Protection Segment is declared to have failed. If the 1:1 IPS Protection Segment is not operational and a candidate Protection Segment becomes operational, that candidate Protection Segment assumes the role of 1:1 IPS Protection Segment, and the 1:1 IPS Protection Segment becomes operational. If a candidate Protection Segment of higher priority than the current Protection Segment becomes operational, then that candidate Protection Segment assumes the role of the 1:1 IPS Protection Segment following expiration of the M:1 wait-to-restore timer. If the current Protection Segment has changed and the 1:1 IPS Protection Segment is the active Infrastructure Segment, then Static Filtering Entries associated with TESIs protected by the IPG are updated with the Port number of the current Protection Segment as described in 26.11.2.2. Thus, M:1 IPS is deployed using an extension of 1:1 IPS that allows the current Protection Segment to be replaced by a candidate Protection Segment of higher priority, provided that such a candidate exists and is operational.

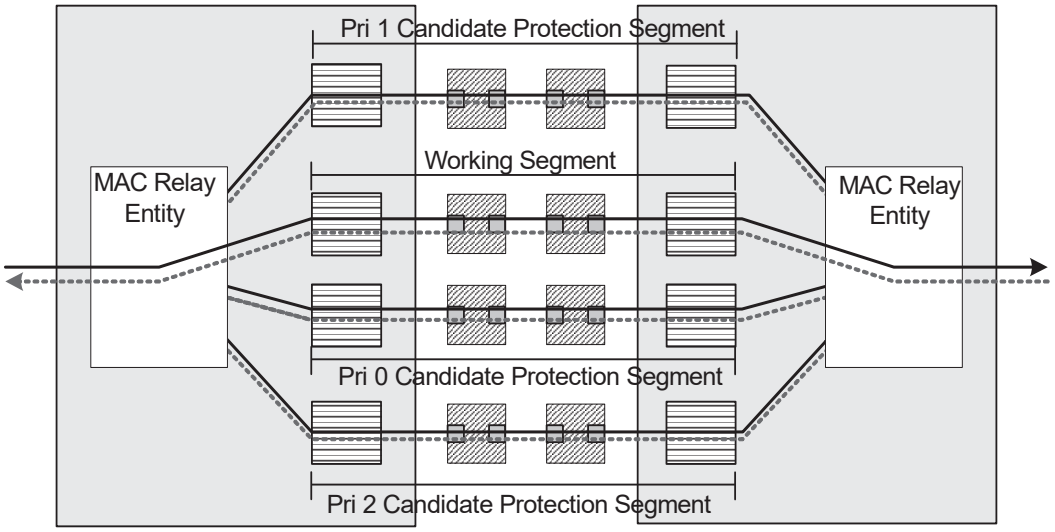

Figure 26-23—M:1 IPS

26.11.5.1 M:1 IPS state machines

There is one set of M:1 IPS state machines per IPG.

The M:1 IPS state machines comprise one M:1 Hold-off state machine (26.11.5.6) per candidate Protection Segment and one Protection Segment Selection state machine (26.11.5.7) per IPG, in addition to the 1:1 IPS state machines (26.11.4). The relationship between the M:1 IPS state machines and the 1:1 IPS state machines is illustrated in Figure 26-24.

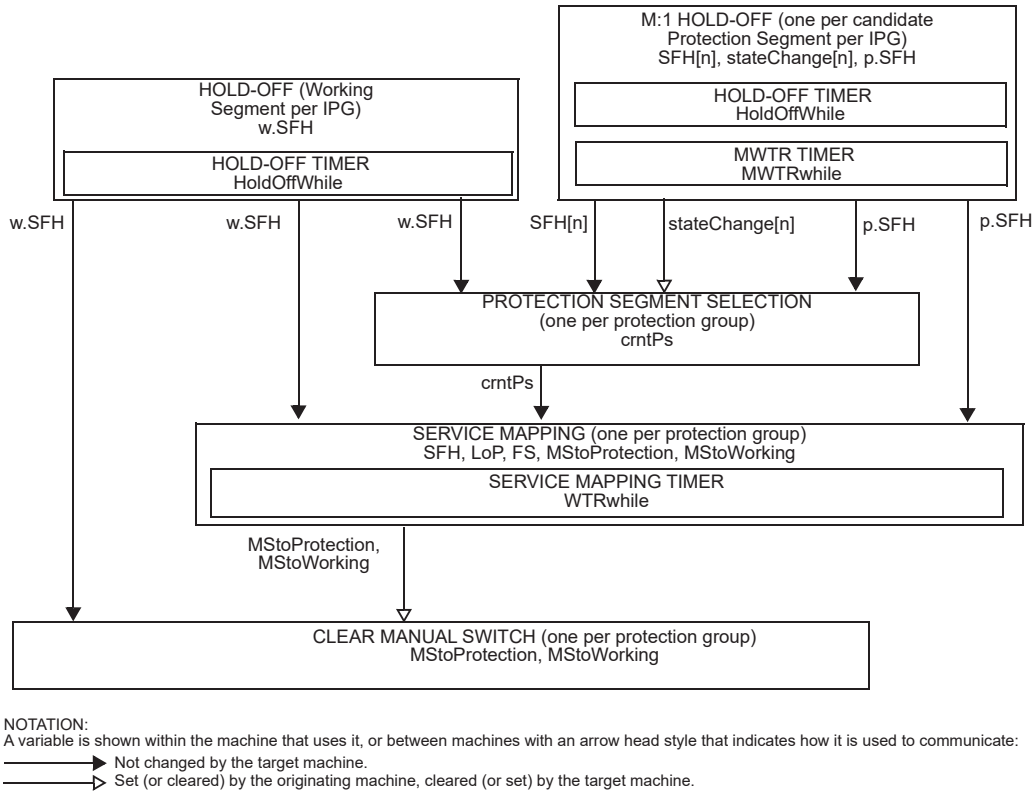

Figure 26-24—M:1 IPS state machines

26.11.5.2 Notational conventions used in state diagrams

The Protection Switching state machines are specified using the notational conventions defined in Annex E. Additionally, in cases of multiple instances of a state variable, each instance is represented by adding the suffix "[n]" to indicate the n^{th} instance. If instances of a state variable may be associated with either the Working Segment or the Protection Segment, the references can be distinguished by prefixing "w." or "p." to distinguish the two cases.

26.11.5.3 State machine timers

The timer variables declared in this subclause are part of the specification of the operation of Protection Switching. The accompanying descriptions of their meaning and use are provided to aid in the comprehension of the protocol only and are not part of the specification. Timer variables deployed by the M:1 IPS state machines are as follows:

a) HoldOffWhile (26.10.3.2.2): one instance per M:1 Hold-off state machine
b) MWTRwhile (26.11.5.3.1): one instance per M:1 Hold-off state machine

26.11.5.3.1 MWTRwhile

A timer to be used to prevent frequent operation of the protection switch among candidate Protection Segments due to an intermittent defect. This timer allows for a fixed period of time to elapse before data traffic is mapped from a lower priority Protection Segment to a higher priority Protection Segment when in M:1 revertive mode.

26.11.5.4 Variables referenced by M:1 IPS state machines

The following variables are referenced by the M:1 IPS state machines:

a) BEGIN (26.11.5.4.1)
b) SF (26.11.5.4.2)
c) SFH (26.11.5.4.3)
d) stateChange (26.11.5.4.4)
e) pri (26.11.5.4.5)
f) allPsSFH (26.11.5.4.8)
g) crntPs (26.11.5.4.6)
h) WTRTime (26.10.3.3.8)
i) MWTRTime (26.11.5.4.7)
j) HoldOffTime (26.10.3.3.9)

26.11.5.4.1 BEGIN

This is a Boolean variable controlled by the system initialization process. A value of TRUE causes all M:1 IPS state machines per IPG to continuously execute their initial state. A value of FALSE allows these state machines to perform transitions out of their initial state, in accordance with the relevant state machine definitions.

26.11.5.4.2 SF

SF is the logical OR of someRMEPCCMdefect (20.35.5), someRDIdefect (20.35.7), xConCCMdefect (20.23.3), and errorCCMdefect (20.21.3). An instance of this variable, identified by the notation SF[n], is specified per candidate Protection Segment.

26.11.5.4.3 SFH

A Boolean flag set and cleared by the M:1 Hold-off state machine to indicate that SF is set for a period that is equal to, or larger than, the HoldOffTime. The variable is set equal to SF if the hold-off timer is not supported. An instance of this variable, identified by the notation SFH[n], is specified per candidate Protection Segment.

26.11.5.4.4 stateChange

A Boolean flag set by the M:1 Hold-off state machine and cleared by the Protection Segment Selection state machine indicating the value of SFH associated with a candidate Protection Segment has changed. An instance of the variable, identified by the notation stateChange[n], is specified per candidate Protection Segment.

26.11.5.4.5 pri

An integer value associated with each candidate Protection Segment and unique within the IPG indicating the selection priority of a candidate Protection Segment. Lower numeric values are associated with higher priority. An instance of the variable, identified by the notation pri[n], is specified per candidate Protection Segment.

26.11.5.4.6 crntPs

An integer value identifying the operational candidate Protection Segment having the highest (lowest numeric) selection priority. In the event that no candidate Protection Segment is available, the value is that of the last candidate Protection Segment to be available.

26.11.5.4.7 MWTRTime

The M:1 wait-to-restore (MWTR) period associated with reverting from a lower priority to a higher priority candidate Protection Segment, as provided by the corresponding managed object [item k) in 12.24.2.1.3]. May be configured by the operator in 1 min steps between 5 and 12 min; the default value is 5 min. A value of 0 indicates M:1 nonrevertive mode. The overall accuracy of the MWTR timer (e.g., <±25 ms) should be sufficient to allow both SEBs at the termination of the IPG to revert to the same value of the Protection Segment in less than 50 ms.

26.11.5.4.8 allPsSFH

The logical AND of the value of SFH[n] over the M candidate Protection Segments.

26.11.5.5 Procedures referenced by M:1 IPS state machines

The following procedures are referenced by the M:1 IPS state machines:

a) highestPriOperPs() (26.11.5.5.1)
b) setPs(n) (26.11.5.5.2) (26.11.5.5.2)
c) mapDataToProtection() (26.10.3.4.2)

26.11.5.5.1 highestPriOperPs()

Returns the identity of the highest priority candidate Protection Segment for which SFH[n] == FALSE or, in the event that SFH[n] == TRUE for all candidate Protection Segments, the value NULL.

26.11.5.5.2 setPs(n)

Establishes the n^{th} candidate Protection Segment as the Protection Segment referenced by the Service Mapping state machine.

26.11.5.6 M:1 Hold-off state machine

The M:1 Hold-off state machine is specified by the state diagram in Figure 26-25 and the variables in 26.11.5.4.

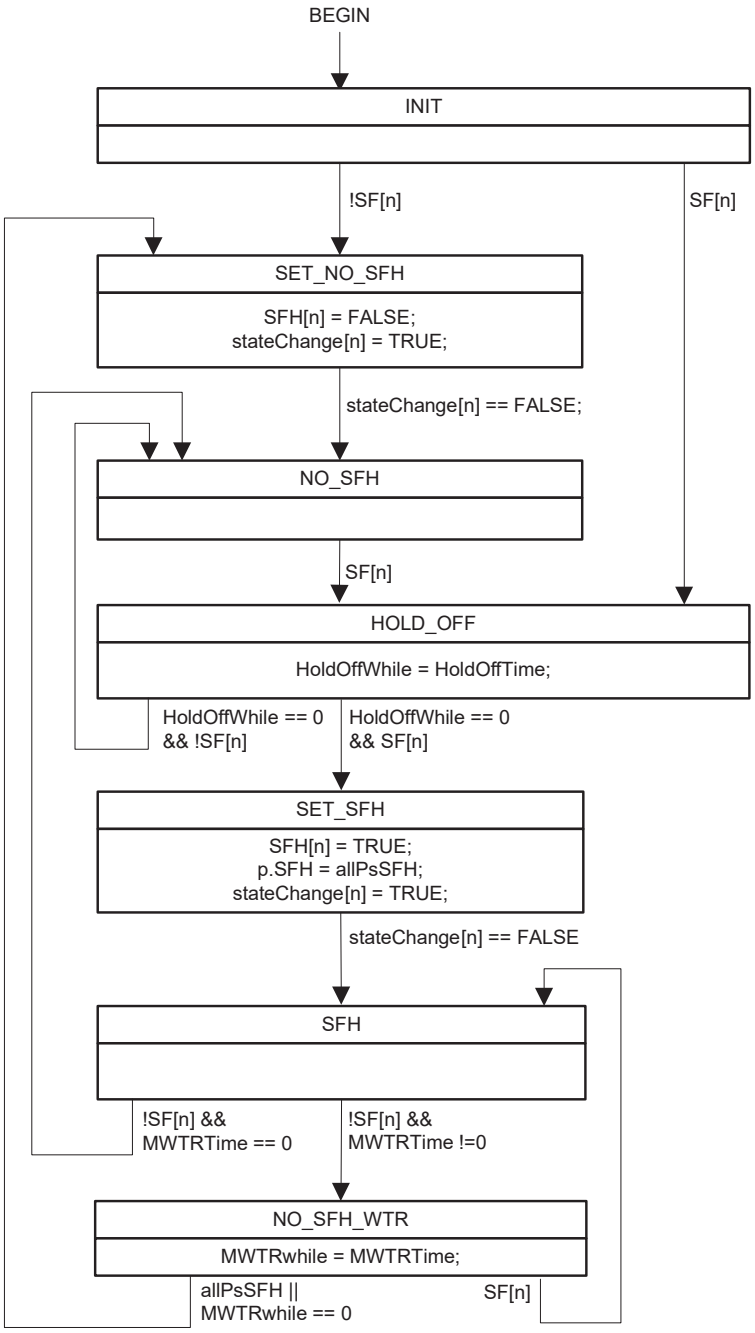

Figure 26-25—M:1 Hold-off state machine

NOTE—The state NO_SFH_WTR is entered only in the case that M:1 reversion has been provisioned (i.e., MWTRTime != 0) and the candidate Protection Segment “n” is operational (i.e., !SF[n]). The state allows the machine to wait a period of time (i.e., MWTRTime) before permitting the candidate Protection Segment “n” to become available for selection as the Protection Segment, thus increasing stability. If, during this time, it is determined that no candidate Protection Segments are available for selection (i.e., allPsSFH), but candidate Protection Segment “n” is operational, then it is prudent not to wait MWTRTime but instead to proceed directly to the selection of candidate Protection Segment “n” as the current Protection Segment. In other words, when no candidate Protection Segment has met the criterion for availability (i.e., allPsSFH), but there is a candidate Protection Segment that is operational (i.e., !SF[n]), then it is not necessary to wait MWTRTime before proceeding with selection.

26.11.5.7 Protection Segment Selection state machine

The Protection Segment Selection state machine is specified by the state diagram in Figure 26-26 and the variables in 26.11.5.4.

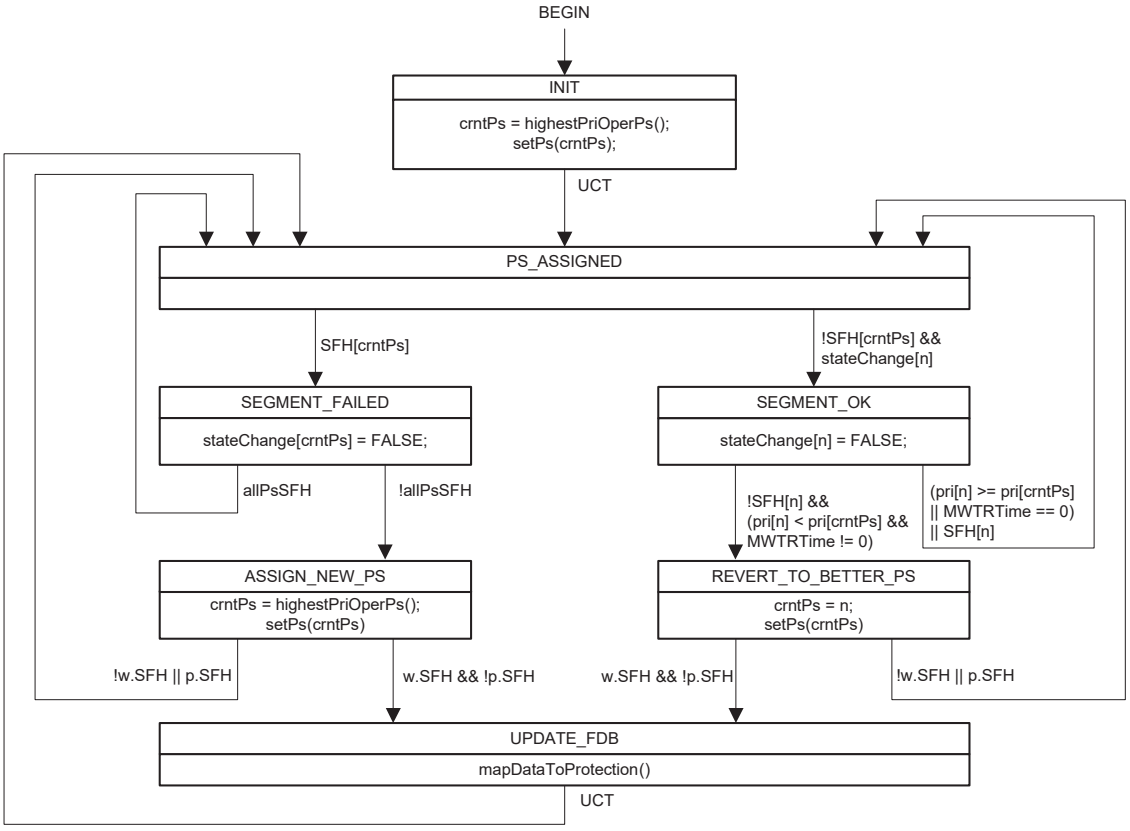

Figure 26-26—Protection Segment Selection state machine

26.12 Mismatch defect

Under equipment malfunction conditions and/or incorrect configuration, a mismatch between the mappings of the backbone service instances to the appropriate TESI at the terminating CBPs can happen. Similarly, a mismatch can occur in the mapping of a TESI to the appropriate Infrastructure Segment at the terminating PNP. To maintain the proper operation of the network, such a mismatch should be detected and reported. There can be two types of mismatch. They are as follows:

a) Protection switching incomplete
b) Working/protection configuration mismatch

An example of protection switching incomplete mismatch is when, due to equipment malfunction, the near end (East B-Component in Figure 26-13) fails to switch over but it sends a CCM with the RDI field set to the far end (West B-Component in Figure 26-13). The far end transmits to the protection TESI while the near end is still transmitting in the working TESI. Similarly a mismatch can also happen when the near end transmits to the protection TESI but the far end fails to start transmitting to the protection TESI when it receives a CCM with the RDI field set.

The mismatch can also happen because of incorrect configuration. For example, one end is configured to send traffic on working TESI while the other end is configured to send traffic on protection TESI. Or one end is configured as revertive mode while the other end is configured as nonrevertive mode. The mismatch occurs when a failure is cleared.

NOTE—Since a merging selector is used, in the case of TESI protection, there is not necessarily a traffic loss in all mismatch cases.

PBB-TE MEPs and Infrastructure Segment MEPs that support the Traffic field (21.6.1.4) can detect such a mismatch. The Mismatch state machine in 20.26 provides this capability.

26.13 Signaling VLAN registrations among I-components

A VIP is a Bridge Port. MVRP can therefore be enabled in an I-component and used to convey dynamic VLAN Registrations from I-component to I-component across a PBBN.

In the particular case of VIPs that do not emit an S-TAG, and thus use only the I-TAG to differentiate among service instances, the Multiple I-SID Registration Protocol (MIRP, Clause 39) can be enabled instead of MVRP (11.2) to signal the need to flush learned C-MAC address information from one Icomponent to another. The network administrator can select between using MVRP or MIRP to perform this signaling according to the need to minimize the number of control frames sent (MIRP) or the number of remote I-components affected by any given control frame (MVRP).

27. Shortest Path Bridging (SPB)

SPB provides shortest path communication for user data frames in SPT regions (Clause 3). ISIS-SPB interoperates with MSTP and RSTP (Clause 13) and STP (Clause 8 of IEEE Std 802.1D, 1998 Edition [B11]), exchanging BPDUs to determine the extent of each SPT Region and to configure full, simple, and symmetric connectivity throughout a network comprising arbitrarily interconnected Bridges and individual point-to-point LANs (13.6, 13.7). IS-IS supports point-to-point links and shared LANs; however, only point-to-point is considered for ISIS-SPB in this specification. A future revision may add shared media. The Clause 13 SPB description allows for both point-to-point links and shared media.

Within an SPT Region (7.4, 13.6), the active topology that supports the frames for any given Base VID can be chosen (27.4) by the network administrator to be one of the following:

— The Internal Spanning Tree (IST).
— A Multiple Spanning Tree Instance (MSTI).
— A set of Traffic Engineering service instances (TESIs).
— A set of shortest path trees (SPT Set), one SPT rooted at each SPT Bridge and supporting frames transmitted into the region through that Bridge.
— Multiple equal cost unicast paths and multicast trees that spread traffic rooted at each SPT Bridge over multiple SPTs. This ECMP connectivity is only supported by SPT Bridges using SPBM mode.
— A set of Explicit Trees (ETs).

Clause 28 specifies the use of ISIS-SPB to calculate the IST and multiple SPT Sets (supporting different ECTs) within an SPT Region. Clause 13 specifies the use of MSTP to calculate MSTIs, and state machines that use the results provided by ISIS-SPB for each SPT to prevent loops within and between regions while maintaining or recovering connectivity as the network reconfigures (13.12, 13.14–13.40, 27.5). The umbrella term ISIS-SPB refers to the coordinated use of the protocols and algorithms specified in Clause 28 and Clause 13 to support SPB.

Clause 45 specifies the use of IS-IS to establish explicit trees within an SPT Region. These trees can differ from the SPTs.

To allow SPB to support plug-and-play operation for some VLANs, while providing the administrative controls and scalability required for large scale operations, this standard specifies two complementary modes of SPT Bridges (SPBV and SPBM) for assigning each shortest path bridged frame to the correct SPT. All the Bridges in a given SPT Region agree on the method to be used to support any given VLAN. Subclause 27.19 describes network scenarios that use one or both of these methods.

If a VLAN is supported by an SPT Bridge using SPBV mode, Shortest Path VIDs (SPVIDs) are automatically allocated by ISIS-SPB and used in VLAN tags within an SPT Region. Each SPVID identifies both the VLAN and the SPT supporting transmission of a tagged frame, and Dynamic VLAN Registration Entries are created to provide connectivity while preventing loops (13.38.2). The SPVIDs for a given VLAN use a single FID that is associated with the Base VID for that VLAN (Shared VLAN Learning (SVL), 7.5, 8.8.8). VID translation (6.9) at the region boundary (7.4, 13.5, 13.12) maps SPVIDs to and from the associated Base VID.

If a VLAN is supported by an SPT Bridge in SPBM mode without ECMP, the Base VID is used in each frame's VLAN tag within the SPT Region and identifies the VLAN and the SPT Set. Each Bridge mitigates and prevents loops (6.5.4, 13.38.2) by using the source and destination MAC address of each frame with Dynamic Filtering Entries for the Base VID, MAC address tuples. The source MAC address identifies the particular SPT from the SPT Set, and supports active topology enforcement (13.38.2, 8.6.1). When forwarding unicast frames it is not necessary to consider the particular SPT since all the SPTs in a given set transiting a given Bridge en route to a destination take the same path from that given Bridge to the

destination (in other words, they are all reverse path congruent with the SPT rooted at that destination). Therefore, for unicast frames the destination MAC address is used for egress filtering as normal. SPT Bridging using SPBM mode requires the use of SPT-specific destination group MAC addresses, so loop-free multicast forwarding is also supported without requiring the source MAC address or source Bridge Port to be part of the FDB query. ISIS-SPB automatically allocates SPSourceIDs (27.10) that are used as part of each group address. Since an SPT Bridge using SPBM mode inspects source MAC addresses as a loop mitigation mechanism, those addresses have to be known before forwarding can take place and are advertised using ISIS-SPB. Learning of B-MAC addresses is not enabled when SPBM mode is used, and frames destined for unknown addresses are discarded and not flooded. The individual MAC addresses used are those of the SPT Bridges themselves, or are associated with functions provided by Provider Bridges or BEB functions that include an SPT Bridge component. SPBM group multicast addresses are local to the SPT Bridge domain [using the Locally administered (U/L) address MAC address flag (IEEE Std 802)], so the use of SPT-specific group MAC addresses does not intrude on the well known global multicast space.

With ECMP (Clause 44), ISIS-SPB can configure multiple potential forwarding Ports for each individual MAC address, and forwarding port selection is performed dynamically. Forwarding Port selection is controlled by a deterministic hash function whose inputs are the SPB System Identifier and the Flow Hash carried in an F-TAG. This tends to spread traffic flows over the set of equal cost paths between the source Bridge and destination Bridge in the SPT Region while preserving frame ordering of individual flows. As a substitute for the loop prevention and mitigation techniques mentioned above, an alternative loop quenching mechanism for ECMP is realized with a TTL field included in the F-TAG. With ECMP, bidirectional and unicast-multicast congruence is no longer guaranteed (since there is no longer a single path in use between a source and destination). This enables each Backbone Service Instance group address to be independently routed and multicast traffic to be spread over a set of equal cost SPTs.

ISIS-SPB uses the same mechanism to allocate SPVIDs (for SPBV) and SPSourceIDs (for SPBM) (27.10). The MST Configuration Identifier (MCID) (8.9, 13.8) is used to ensure that all the Bridges in an SPT Region agree on the method used to support each shortest path VLAN and on the pool of SPVIDs, as well as on the other uses of VIDs (27.4). An SPSourceID is allocated to each Bridge in an SPT Region, independently of SPBM mode VLANs, while an SPVID for a given SPBV VLAN is only allocated to the SPT rooted at a given Bridge if VLAN Registration Entries and controls allow that Bridge to transmit frames assigned to that VLAN into the region (8.8, 13.6).

An SPT Bridge using SPBV mode is typically used to support a C-VLAN or S-VLAN for a single customer. An SPT Bridge using SPBM mode is typically used to support B-VLANs in PBBNs (Clause 25). Each B-VLAN can support many backbone service instances, each requiring connectivity between a subset of the BEBs participating in the B-VLAN, and each identified by an I-SID that is not processed by BCBs. An SPT Bridge using SPBM mode does not use source address learning, so unicast B-MAC frames conveying customer data are never flooded throughout the B-VLAN. Multicast frames and flooding of unknown unicast frames for a given backbone service instance are confined to paths that reach the BEBs supporting that service instance by including the I-SID in the SPT-specific destination group MAC addresses (Figure 27-3). The destination address filtering in each BCB prunes transmission of the encapsulated customer multicast frames as well as preventing loops.

MVRP (11.2) is not used within SPT Regions, as ISIS-SPB communicates VLAN registration information for VLANs supported by SPB from the SPT Bridges that provide ingress to and egress from the region to the other Bridges, thus allowing SPT Bridges using SPBV and SPBM to configure Dynamic VLAN Registration Entries for Bridge Ports within the region to provide correct VLAN connectivity when SPTs are recalculated—instead of waiting for registration information to propagate on those SPTs. SPT Bridges can use the registration information communicated within the SPT Region to participate in MVRP with Bridges outside the region (27.13) by supporting MVRP interfaces on the Region boundaries.

This clause specifies the following:

a) Protocol design and support requirements (27.1, 27.2) and design goals (27.3).

This clause further specifies how:

b) Each Bridge's configuration mechanisms specify the supporting method (SPBV, SPBM, MSTI, CIST, or PBB-TE) and SPT Set (for SPBV and SPBM) for each VLAN (27.4).
c) The boundaries of each SPT Region and ISIS-SPB adjacencies are determined dynamically by ISIS-SPB (Clause 28).
d) The information exchanged by ISIS-SPB is used (27.5), including CIST calculation (27.6, 27.7), SPT calculations (27.8), allocating SPVIDs and SPSourceIDs (27.10), and controlling the connectivity supporting each VLAN (27.13) and backbone service instance (27.15, 27.16).
e) The results of ISIS-SPB's CIST and SPT calculations are used by the Clause 13 state machines to determine when to discard frames to ensure the calculated trees are loop-free (27.9).
f) SPVIDs are allocated to FIDs (27.11) and translated to and from Base VIDs at the boundary of an SPT Region (6.9, 13.6).
g) VLAN Registration Entries are used to forward or discard frames for each VLAN (27.13).
h) FDB entries for individual addresses are used to prevent or mitigate loops for VLANs supported by SPBM (27.14).
i) SPBM Group Addresses are assigned, and FDB entries for those addresses used to forward or discard frames for each backbone service instance for B-VLANs supported by SPBM (27.15, 27.16).
j) The SPT calculations choose between Equal Cost Trees (ECTs), making different choices for different SPT Sets, each associated with a different VLAN, enabling load spreading (27.17, 28.9.2).

This clause also:

k) Provides examples of when and how SPT Bridges using SPBV and SPBM modes can be used (27.19).

27.1 Protocol design requirements

ISIS-SPB configures entries in each SPT Bridge's FDB (8.8) to meet the following requirements:

a) The active topology will fully connect all physically connected LANs and Bridges, and stabilize (with high probability) within a short, known bounded interval after any change in the physical topology, maximising service availability (8.4).
b) Except in the case of ECMP, the active topology for any given frame remains simply connected at all times (6.5.3, 6.5.4).
c) The same symmetric active topology is used, in a stable network, for all frames for the same VLAN, i.e., between any two individual LANs those frames are forwarded through the same Bridge Ports.
d) The active topology supporting a given VLAN within an SPT Region can be chosen by the network administrator to be shortest path, the IST, an MSTI, or an ET.
e) Each active topology is predictable and reproducible, and may be influenced by management, thus allowing the application of Configuration Management following traffic analysis, to meet the goals of Performance Management (6.5 and 6.5.10).
f) The configured network can support VLAN-unaware end stations, such that they are unaware of their attachment to a single LAN or a bridged network, or their use of a VLAN (6.3).
g) The SPB mode, SPBV or SPBM, can be chosen by the network administrator independently for each VLAN using shortest paths.

SPBV mode meets the following requirements:

h) No additional constraint is placed on the values of the Individual or group MAC addresses used, and those addresses do not have to be known before being used in data frames.

i) SPVIDs are allocated to every SPT Bridge that is a potential source of frames on VLANs supported by SPBV.

j) FDB entries for a given SPVID will only be populated if they are on the shortest path to a participating boundary node.

SPBM mode meets the following requirements:

k) Multicast flooding for each backbone service instance supported by a PBBN is restricted to paths necessary to reach BEBs supporting that service instance.

l) ECMP operation enables multiple equal cost paths in the SPT Region to carry a share of unicast and multicast traffic.

NOTE—The ECMP ECT Algorithm supports multicast load spreading over up to 16 source trees per node and up to 16 shared trees.

Additionally, SPB algorithms and protocols meet the following goals, which limit the complexity of Bridges and their configuration:

m) The memory requirements associated with each Bridge Port are either a constant or a linear function of the number of Bridges and LANs in the network.

n) The communications bandwidth consumed by ISIS-SPB on any particular LAN is always a small fraction of the total available bandwidth (6.5.10).

o) Bridges do not have to be individually configured before being added to a network, other than having their MAC addresses assigned through normal procedures.

27.2 Protocol support

ISIS-SPB is configured to use one of the Group addresses from Table 8-16 to establish adjacencies and exchange PDUs. SPB running on C-VLAN components use the Customer Bridge address. SPB running on S-VLAN components use the Provider Bridge address. SPB running on B-VLAN components may use the Provider Bridge Address or one of the existing IS-IS addresses.

The use of the ISIS-SPB adjacency between Bridges is contingent on the Bridges inclusion within the same SPT Region, and thus requires they have an MCID and Auxiliary MCID (13.8, 28.12.2) where at least one matches on every adjacency in the Region (8.9.4, 13.8). MCID and Auxiliary MCID enable migration of the MCID definition allowing these Bridges to operate as one SPT Region under certain small changes. The operational set of Base VLANs and SPVIDs must be consistent during migration. This standard specifies default configurations resulting in a MCID that enables plug-and-play support of both the CIST and SPB using SPT Bridges using SPBV mode. No default recommendations are made for SPT Bridges using SPBM mode, since it is only expected to be used in managed environments.

This standard recommends defaults for Bridge and Bridge Port priorities and path costs to support the calculation of active topologies without further configuration. To allow management of those active topologies, a means of assigning values to the following are required:

a) The relative priority of each Bridge in the network (13.26.3)

b) The relative priority of each Port of a Bridge (13.27.47)

c) A Port Path Cost for each Port (13.27.25, 13.27.33)

Management of SPT topologies and of the use of SPBV or SPBM mode to support particular VLANs, also requires the following:

d) Management of the SPB objects (12.25)
e) Administrative agreement on the MCID Configuration Name and Revision Level (Clause 28)

27.3 Protocol design goals

It is highly desirable that the operation of ISIS-SPB allows the following:

a) Addition of Bridges to an existing SPT Region without disrupting existing communication
b) SPB support for additional VLANs without disrupting existing communication
c) Enabling or disabling SPB support for individual VLANs with minimum frame loss

27.4 ISIS-SPB VLAN configuration

The configuration mechanisms used by MST Bridges to allocate each VLAN to a specified MSTI or the IST within an MST Region and used to allocate VIDs for PBB-TE (25.10) can be summarized as follows:

a) The VID to FID allocation table (8.8.8, 12.12.2) is used to allocate each VID to a FID.
b) The FID to MSTID Allocation Table is used to associate an MSTID with a FID (8.9.3, 12.12.2):
    1) The IST is identified by the reserved MSTID value 0.
    2) The use of PBB-TE is identified by the reserved MSTID value TE-MSTID (0xFFE)
    3) Each MSTID in the MSTI List identifies an MSTI.
    The reserved MSTID values 0 and TE-MSTID, SPBV-MSTID, SPBM-MSTID, and SPVID-Pool-MSTID are never used in the MSTI List.

SPT Bridges extend these configuration mechanisms as follows:

c) The VID to FID allocation table is used to allocate Base VIDs to FIDs, and to allocate VIDs for use as SPVIDs. SPVIDs are allocated to the reserved FID value 0xFFF. SPVIDs in use are reported by management as allocated to a FID supported by the implementation (27.11).
d) The reserved FID value SPVID-Pool-MSTID is allocated to the reserved MSTID value 0xFFF.
e) The following MSTID values identify the SPT Bridge mode used by SPB:
    1) 0xFFC—SPBM
    2) 0xFFD—SPBV

This standard recommends default VID to FID and FID to MSTID allocations (27.2, 8.9.3) for SPT Bridges that enable plug-and-play support of both the CIST and SPB using SPBV mode.

Table 27-1 shows the VID to FID and the FID to MSTID allocation tables in a single table for the configuration example shown in Figure 27-1 for an SPT Region.

Base VID 1 is allocated to the IST and VIDs from 0x100 to 0x1FF form the SPVID Pool. Base VIDs 0x002, 0x003, and 0x004 are configured to operate in SPBM mode. Base VIDs 0x005, 0x006, and 0x007 operate in SPBV mode in the example.

Table 27-1—Allocation of VIDs to FIDs and FIDs to MSTIDs in an SPT Region (example)

VID	FID	MSTID
0x001	0x001	0x000
0x002	0x002	0xFFC
0x003	0x003	0xFFC
0x004		
0x005	0x005	0xFFD
0x006	0x006	0xFFD
0x007		
0x100–0x1FF	0xFFF	0xFFF

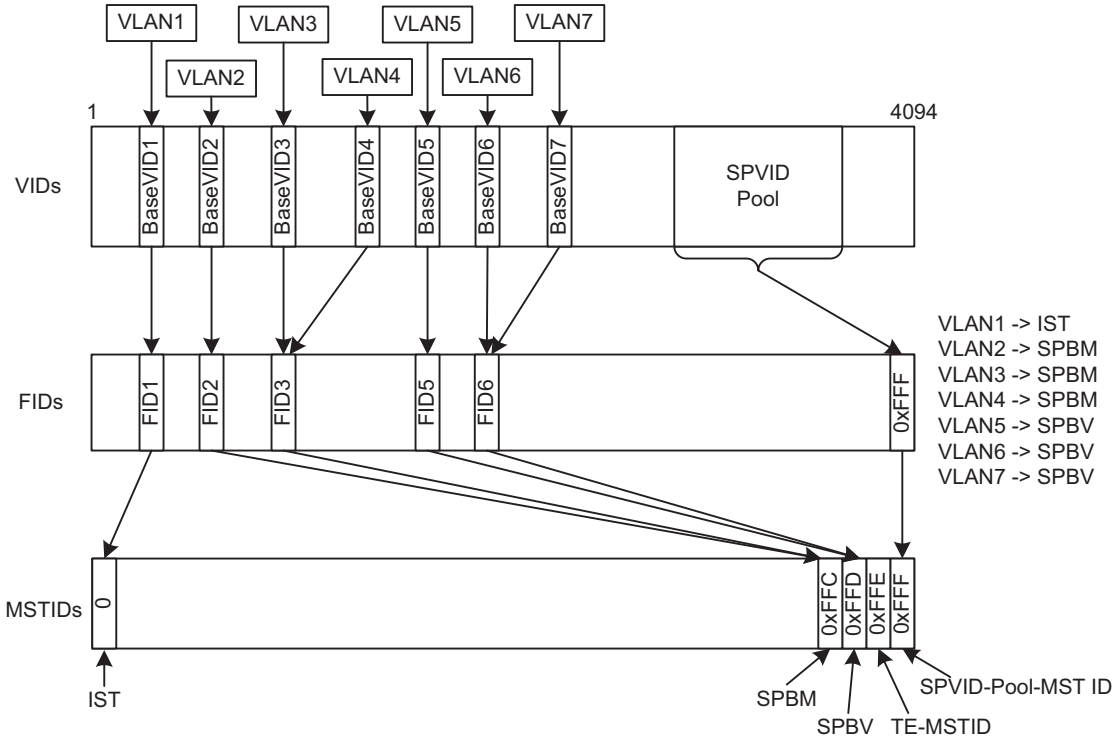

Figure 27-1—Configuring VLAN support in an SPT Region (example)

27.4.1 SPT Region and ISIS-SPB adjacency determination

It is essential that all Bridges within an SPT Region agree on the allocation of VIDs to spanning trees prior to transmission and reception of frames tagged with those VIDs. This configuration requirement is common to both SPB (13.6) and MSTP operation (13.5), and MSTP can coexist with ISIS-SPB within an SPT Region, supporting different VLANs with different VIDs. ISIS-SPB uses and extends MSTP's configuration mechanisms and use of the MCID (8.9, 13.5, 13.8). Note the MCID (13.8) includes a digest derived from the mapping of VIDs to MSTIDs. To allow dynamic manipulation of SPVIDs without impacting the MCIDs, the mapping of SPVIDs to the FID associated with the supported Base VID is not captured in this table.

SPB configuration is highly automated. An SPT Region is created by configuring at least two adjacent Bridges with compatible information. The region grows dynamically as more SPT Bridges with the same region configuration are introduced. Once a region has been created, other VLANs can also be created. ISIS-SPB will populate forwarding only between Bridges that support the same services. The SPT region is an interconnected set of Bridges supporting the Region configuration [MCID (13.8), ISIS-SPB Configuration (27.4)] but the forwarding for any one VLAN is simply the Bridges configured to support services on that VLAN or the Bridges that lie on the shortest path between those Bridges.

The same is true of SPT Bridges operating in SPBM mode that can be added to support new VLANs on a Bridge by Bridge basis. One common operation for SPT Bridges operating in SPBM mode is to create a new ECT for a new VLAN. To support a graceful migration of services to a new Base VID, SPB allows the configuration of the Base VID before configuring services on those Base VIDs. The new Base VIDs in SPT Bridges need to be configured on all Bridges where the services reside. The U-bit (28.12.5) and Use-flag (28.12.4) are used to identify configured Base VIDs that do not have active services associated with them.

In the cases where the allocation of Base VIDs is insufficient a graceful way to support an increase in the number of Base VIDs is supported by a second (auxiliary) MCID (13.26.8, 28.12.2). Two such Bridges consider themselves to be in the same MST Region provided that at least one of their MCIDs matches with one of their SPB neighbor's MCIDs. Non critical changes in the MCID, can be made while maintaining forwarding on the previous configuration. This is done by configuring a Bridge with a revised VID allocation that is compatible with the current allocation in use for SPB forwarding. The Bridge advertises this new MCID and continues to advertise the previous MCID as the Auxiliary MCID, maintaining its adjacencies.

When an adjacent Bridge is similarly configured, it also advertises the new MCID as its MCID to its adjacencies. The Auxiliary MCID is always the outgoing MCID. Bridges that have not been updated will continue to match their updated neighbors' Auxiliary MCID until they have been updated, whereupon their MCID values will match again. When a Bridge sees that all its adjacencies are advertising the value of its own new MCID as their MCID, then the Bridge shall start advertising the value of its new MCID as its Auxiliary MCID also. When all Bridges have been verified to have installed the new configuration, the transfer of services to use the new VLAN allocations may be administratively initiated.

NOTE 1—The MCID verifies that each Bridge in the region agrees how each and every Base VID is to be assigned to the IST, to an MSTI, for use by PBB-TE, for support by SPBV mode, for use as an SPVID, or for support by SPBM mode. The MCID does not specify the SPT Set for VLANs supported by SPB, or preallocate SPVIDs to SPT Sets as disagreement on the former or temporary differences in the latter will not cause permanent loss of connectivity, loops, or protracted flooding. ISIS-SPB verifies that SPT Bridges agree on the SPT Set to be used to support any given SPB supported VLAN, and the Agreement Digest ensures that new connectivity is not created until that agreement has been reached.

NOTE 2—The MCID and the Agreement Digest (13.8, 28.4) can both influence the connectivity provided, and their respective roles need to be clear. MCID differences identify configuration mismatches that could cause network malfunction (e.g., data loops) if connectivity were to be created, and that are not amenable to timely resolution by normal protocol operation. MCID differences act as a fail-safe mechanism, forcing lowest common denominator connectivity (to a single spanning tree, the CST) so at least some connectivity is provided, albeit with lower throughput. The fallback connectivity can be used to investigate or correct configuration issues. The Agreement Digest and related mechanisms simply verify that delays in propagating and using protocol information do not cause loops in permitted connectivity.

SPT Regions are similar to MST Regions, and can also be modeled as single Bridges (13.5.3). They do not overlap, superset, or subset other regions but participate in the same active topology solely through the CST. Each region can be identified by its Master Port, i.e., the Bridge Port that provides connectivity from the region to a CIST Root that lies outside the region, or, in the case where the CIST Root lies within the region, by the CIST Root Bridge itself. The Master Port is uniquely and globally identified by its Bridge Identifier and Port Identifier on an SPT Bridge, and is communicated by the CIST Regional Root Identifier and its associated CIST Port Identifier fields in SPT BPDUs.

IS-IS adjacencies are formed according to IS-IS protocol rules independent of ISIS-SPB. ISIS-SPB forwarding is only allowed on a more strict basis when the MCID, Base VID, and ECT Algorithm information lines up in the SPB Hello PDUs.

When two SPT Bridge Ports attached to the same LAN have no match between their primary or Auxiliary MCIDs in transmitted SPT BPDUs, each is a Boundary Port (13.12) for its SPT Region, and forwards user data frames only if it is a CST Root Port or Designated Port. Such a network configuration is usually temporary and infrequent, a result of as yet incomplete administrative action, or simply a configuration error (13.6). To minimize network disruption during such administrative episodes, ISIS–SPB communicates information throughout an SPT Domain comprising a transitive closure of SPT Bridges attached to individual LANs.

Each SPT Bridge Port uses BPDUs and/or SPB Hello PDUs to transmit and receive MCIDs and Agreements. BPDUs also carry currently calculated CIST Information, so that all the Bridges (not just SPT Bridges) attached to each individual LAN can be detected and can participate in the information exchange required at SPT Region boundaries. SPT BPDUs or SPB Hello PDUs also convey the CIST Agreement and Agreement Digest information that SPB uses to prevent temporary loops (28.4). This Agreement information can only be sent after the Bridge's ISIS-SPB calculations have been used to modify its FDB entries, and is thus not naturally tied to the transmission of the ISIS-SPB Link State PDUs (LSP)s that convey the adjacency information that makes those calculations possible (LSPs can be disseminated throughout the SPT Domain without waiting for any single Bridge to complete its calculations—each proceeding in parallel). Including the Agreement information in the SPT BPDUs helps determine the SPT Region's extent, ensuring backwards compatibility to non SPT Bridges. Exchanging SPB Hello PDUs (to establish adjacencies) and transmitting ISIS-SPB LSPs (to propagate information for SPT Identifier allocation and SPT calculation throughout the SPT Domain) as soon each Bridge Port is MAC_Operational is supported in parallel with BPDUs. Bridges that are not SPB-capable will not support SPB Hello PDUs and it is up to the SPT BPDU logic to determine what type of spanning tree protocol the non-SPT Bridges support. In most networks the SPT Region's boundary will coincide with that of the SPT Domain, in other cases LSPs for those Bridge Ports that bound a region but lie within the domain might have to be transmitted.

NOTE 3—Clause 13 specifies the state machines and procedures that determine each SPT's region boundaries, including interoperability with Bridges implementing STP (Clause 8 of IEEE Std 802.1D, 1998 Edition [B11]), RSTP, or MSTP as well as the use of SPT BPDUs to address other error conditions that can occur (e.g., disputes with other Bridges due to one-way connectivity).

27.5 ISIS-SPB information

ISIS-SPB can be viewed primarily as a means of sharing information between nodes in a network, providing each node with a copy of a common database of information contributed by each and every node, and ensuring (with high probability) that the copies are kept up to date though not necessarily in lock step synchronization. Each node can then execute its own independent copy of one or more previously agreed algorithms that use that node's copy of the database to compute results that are common to all the nodes, or that are part of a common or complementary set. The result is a set of forwarding tables for each node. ISIS-SPB shares information throughout an SPT Domain so that any given SPT Bridge in the domain can calculate or identify the following:

a) The CIST connectivity provided to each SPT Bridge in the domain (27.6, 27.7). This calculation identifies each of the SPT Regions within the domain (if more than one, 8.9, 13.6), the Bridges in each region, and the CST connectivity between regions.
b) The SPB connectivity provided by each SPT Set between Bridges in the given Bridge's region (27.8).
c) The SPVIDs (for SPBV mode) and SPSourceIDs (for SPBM mode) used to support SPB connectivity (27.10).
d) The VLAN connectivity provided for each Base VID over the calculated tree(s) (27.13).
e) The connectivity provided for each I-SID by the SPT Bridge over the calculated tree(s) (27.16).

27.6 Calculating CIST connectivity

ISIS-SPB calculates CIST connectivity (13.4.1, 13.5.3) using the following information from each Bridge in the SPT Domain:

a) The Bridge Identifier and, if the Bridge has currently selected its CST Root Port using information received from a Bridge that is not in the SPT Domain:
   1) The CIST Root Identifier and CIST External Root Path Cost.
b) The Port Identifier and the following information for each of the Bridge's Ports:
   1) Its IS-IS adjacencies, i.e., a list of the Bridge Identifier, Port Identifier tuples that identify each of the other SPT Bridges attached to the same LAN.
   2) Whether the Bridge Port is or is not a Boundary Port (13.12).
c) For each of the Bridge's Ports that is not a Boundary Port:
   1) The Internal Port Path Cost.
d) For each of the Bridge's Ports that is a Boundary Port:
   1) The External Port Path Cost.

If the restrictedDomainRole (13.27.63) parameter is set for an SPT Bridge Port, then that port will not be selected as a CIST Root Port if the Designated Bridge for the attached LAN is not in the SPT Domain. Used arbitrarily restrictedDomainRole and restrictedRole (13.27.64) can cause lack of connectivity. If used to support the network design these parameters can speed network convergence and protect against disruption if inappropriately configured Bridges are attached. If configured for all SPT Bridge Ports, restrictedDomainRole ensures that the CIST Root and all connectivity to and from that CIST Root will be provided solely by Bridges within the SPT Domain, thus simplifying CIST calculation. An SPT Bridge implementation may choose to always set restrictedDomainRole, managing it as a read only parameter. This choice restricts network design, but can include all scenarios intended for the implementation (27.19).

The CIST calculation uses the Dijskstra algorithm to compute the same active topology that would be produced by the distributed distance vector calculation specified in 13.10. Computation begins with the best priority CIST Bridge priority vector from those that represent each of the Bridges within the domain as a potential root and from those reported as received from a Bridge outside the domain [item a1) above]. If the External Path Cost accumulated during the computation would exceed that for a Bridge selecting its CST Root Port using information from a Bridge outside the domain, then that Bridge is also marked as having been reached in spreading computation and can be the best path to further Bridges, indicating that the CST path between SPT Regions lies outside the domain (not always a temporary or undesirable result, 27.19).

NOTE 1—The purpose of defining *priority vectors* (13.9) is to allow all the components that contribute to the choice of one path or another to reach a given Bridge or LAN from the CIST Root to form part of a single metric.

Each Bridge in the SPT Domain performs the CIST calculation independently, computing and retaining the following information for use by the state machines specified in Clause 13 (13.10, 13.17, 13.36, 13.29.34):

e) The CIST root path priority vector for every Bridge Port on the Bridge and the CIST root priority vector for the Bridge.
f) The IST Port Role for each of the Bridge's Bridge Ports that is not a Boundary Port.
g) The CIST designated priority vector for each of the Bridge's Bridge Ports.

Each Bridge's CIST calculation also identifies the following:

h) The SPT Region for itself, and for each of the other Bridges in the domain.
i) The CST Port Role for each Bridge Port that is a Boundary Port for a region.

NOTE 2—Each SPT Region can be identified by the region's Master Port. Connectivity from all Bridges in a given region, R_1 say, passes through the same Boundary Port BP_{12}, to reach any Bridge in a region R_2. Recording the region and boundary port information during CIST calculation facilitates identification of the boundary Bridges.

27.7 Connectivity between regions in the same domain

If the SPT Domain has been found to comprise more than one region, then, prior to computing shortest paths, each Bridge uses the SPT Region and CST Port Role information [item h) and item i) in 27.6] computed for each Boundary Port together with the adjacency information for those ports to determine the following:

a) For each of the regions (R_2, R_3, ... say) other than the computing Bridge's own region (R_1, say), the Boundary Bridge (B_{12}, B_{13}, ...) within R_1 that provides CST connectivity to that region.

If the connectivity between regions lies outside the domain and either has (or has IST connectivity to a region that has) more than one Bridge that provides connectivity to a Bridge outside the domain, then ISIS-SPB does not have the information necessary to select a particular Boundary Bridge. Address learning (for SPBV) or registration protocols can provide the necessary information. If more than one possibility remains, an SPT Bridge using SPBM mode cannot provide connectivity between the regions.

NOTE—SPBM mode will often be configured to permit connectivity only if the entire path lies within the domain.

27.8 Calculating SPT connectivity

Each SPT Bridge uses ISIS-SPB to calculate the shortest paths from each of the Bridges [item h) in 27.6] in its own SPT Region including itself, to each of the other Bridges in that region. The information used by ISIS-SPB to perform the necessary Dijkstra calculations is a subset of that used for the CIST calculation [item a), item b1), item c1) in 27.6]. The following information is computed for each SPT and retained for use by the state machines specified in Clause 13 and 27.9, 13.17, 13.36, and 13.29.34:

a) The root priority vector for the Bridge.

and for each of the Bridge's ports that is not a Boundary Port:

b) The Port Role.
c) The designated priority vector.

and for each of the Bridge's ports that is not a Boundary Port and has a Port Role of Designated Port:

d) The best root path priority vector out of those that would be calculated, using the same ISIS-SPB information, by the other SPT Bridges.

There can be several equal cost shortest paths between any given pair of Bridges, but unless ECMP is in use, only one path between the pair can be used in a given SPT Set. Ties are broken using an algorithm (27.17, 28.5) that is independent of the order of SPT computation, that ensures that the SPTs in each SPT Set are symmetric, that allows path selection to be managed using the same variables that are used to manage active topologies in the absence of multiple paths, and that is likely to select different equal cost paths for different SPT Sets if configuration defaults are used.

When a VLAN is supported by an SPT Bridge using SPBM mode and loop mitigation (6.5.4.2, 27.14) is being used, each of the FDB entries that control forwarding for unicast frames can be created or modified as soon as the port providing the shortest path to the Bridge or end station using that address is known, without the need to use additional protocol or to complete the SPT computation. In that case, restoration of unicast connectivity after a physical topology failure is most rapidly achieved by beginning the SPT (re)computation with the SPT rooted at the calculating Bridge.

27.8.1 ISIS-SPB overload

IS-IS has an overload capability that applies to a node that does not allow transit traffic through this node for various operational reasons. This capability has also been added to ISIS-SPB [item c in 28.12.1] TLVs. Just as in normal IS-IS Overload modifies the shortest path results by not allowing Bridges with the overload bit set to be eligible to forward transit traffic. For the purpose of computing paths, any paths through Bridges with overload set are not considered shortest paths and the computation uses the remaining topology and the next shortest paths. Use of the overload condition is typically reserved for edge devices that would not benefit the network if they were to become transit switches.

In ISIS-SPB if overload were set in the only Bridge connecting an SPT Region this would result in a region split where the overload Bridge was connected to both halves of the region but traffic could not transit through the overload Bridge. Each section of the SPT Region that is split would behave normally but there would be incomplete connectivity between the split sections. ISIS-SPB would have a complete view of the region and this condition is relatively easy to detect.

27.9 Loop prevention

The state machines in Clause 13 use the calculated priority vectors and Port Roles for each tree (27.6, 27.8) to determine the tree's Port State (i.e., the setting of the per port learn (13.27.34) and forward (13.27.29) variables), and exchange SPB BPDUs or SPB Hello PDUs to convey Agreements (13.17) that allow these variables to become set for Root Ports, Designated Ports, and Master Ports without the risk of temporary loops.

The Port State Transition state machine (13.38) signals changes to the learn and forward variables for a port for the CIST through calling disableLearning(), disableForwarding(), enableLearning(), and enableForwarding() procedures. These implementation-dependent procedures prompt changes to the mechanisms that perform forwarding and/or learning for frames assigned to the CIST.

Similarly changes to forward for a port for an SPT prompt changes in the FDB entries that allow (or prevent) the ingress or egress of frames assigned to that SPT (27.13, 27.14, 27.16). In turn these prompt changes to the implementation-dependent mechanisms that use the entries to control forwarding.

These mechanisms can take time to respond to changes in learn or forward, and report their current state to the state machines (by setting the learning (13.27.35) and forwarding (13.27.30) variables) so that new connectivity on some ports can be made contingent on other ports not forwarding frames. The forwarding variable (for any given tree) is only cleared if frames assigned to that tree neither ingress nor egress the port.

27.10 SPVID and SPSourceID allocation

Each SPT Bridge uses ISIS-SPB to support the distributed allocation of SPVIDs (used by SPBV mode) and the 20-bit SPSourceIDs (used by SPBM mode), ensuring that all Bridges in the SPT Domain agree on the allocated values. The allocation protocol for these two types of identifier differs slightly, as a consequence of the differences in the number of values available and the number required for each Bridge.

Candidate values for these identifiers may be pre-configured, in some or all of the Bridges in the domain, but by default they are allocated dynamically. Each Bridge attempts to allocate the following values:

a) An SPSourceID for the Bridge.
b) An SPVID for each VLAN that is supported by an SPT Bridge using SPBV mode and for which:
    1) The Bridge is a potential source of frames, either from a protocol entity within the Bridge or by forwarding from a port on the Bridge that is a Boundary Port; or
    2) The Bridge has a pre-configured allocation, even if conflict resolution means that this allocated value is not used.

NOTE 1—Each SPT Bridge allocates an SPSourceID even if no VLANs are to be supported by SPBM mode, or the Bridge is configured not to transmit frames for those VLANs. The number of available SPSourceIDs is much greater than the number to be allocated; therefore, there is no need to complicate allocation scenarios by attempting to optimize some cases, however frequent.

NOTE 2—If the SPT Bridge does not have a pre-configured SPVID for a VLAN supported by SPBV mode, and has no need to transmit frames for that VLAN (possibly because there is no other Bridge in the domain that wishes to receive frames for the VLAN or because a VLAN Registration Entry does not allow the Bridge to transmit frames for that VLAN), then an SPVID is not allocated. These conditions can arise even if the Base VID to FID to MSTID configuration for the Bridge, and the resulting MCID, identifies the VLAN as supported by SPBV mode.

The allocation protocol resolves conflicting attempts by different Bridges. Pre-configured or dynamic allocations are communicated by the setting of the Configuration Flags in the ISIS-SPB TLV used for allocation. Conflicts for allocations of a given type are resolved by granting the allocation to the Bridge with the best priority (numerically least) Bridge Identifier (14.2.5). When the conflict occurs on an auto allocated value, the other Bridges attempt to satisfy their need for a value by changing their allocation to a new dynamically allocated value. In the case that two configured values conflict, these must be resolved by operator action. All Bridges are aware of these conflict resolution rules, so there is no need for additional protocol to confirm or announce the allocation.

Candidate values for dynamic allocation are chosen using a pseudo-random function of each Bridge's Bridge Identifier (thus reducing the chance of only one identifier being allocated each time all the Bridges transmit fresh allocation information). Values that the allocating Bridge knows to be already in use are excluded (thus ensuring that an allocation that has been in existence long enough to be included in the IS-IS database of all Bridges in the domain will not be disrupted). Assuming that the unallocated values are arranged as an ordered list, the Bridge performs a modulo operation on its Bridge Identifier by the number of free values, and selects the indicated value from the list. This operation is repeated to select the next candidate value.

NOTE 3—When a Bridge changes its allocations, i.e., allocates new values to itself as required for (a) or (b) above or releases existing values, ISIS-SPB will communicate the updated information to the other Bridges in the domain. However, the detailed transmission timing and the other contents of IS-IS PDUs is under the control of ISIS-SPB itself, and is not directly controlled by the allocation protocol. A single PDU will usually convey a number of allocation changes.

NOTE 4—SPT Bridges can use different pseudo-random candidate selection functions, without imperiling the eventual success of the protocol. Nonetheless, SPVID allocation conflicts are likely to be fewer, and more quickly resolved, if the Bridges in a domain use the same algorithm.

On first discovering an ISIS-SPB adjacency (27.2, Clause 3) an SPT Bridge does not perform any allocation before acquiring the IS-IS database. The SPT Bridge becomes aware of existing allocation through normal IS-IS operation. While acquiring the full IS-IS Database, the Bridge advertises SPSourceID = 0 in its LSPs, to indicate to other Bridges that it shall not be included in Shortest Path First (SPF) calculations. As soon as the Bridge has successfully allocated itself an SPSourceID, this allocated value shall be advertised in ISIS-SPB. If the Bridge is aware of dynamic allocations that it has been granted in the past, it may begin by retrying those allocations rather than performing a pseudo-random selection for each that is free.

Each SPT Bridge ages out the allocations, both configured and dynamic, made by other Bridges exactly as the allocation information ages out or is replaced in the IS-IS database.

Each SPT Bridge's SPSourceID can be any one of the possible 2^{20} values, of which a small number (less than 2^{10}) are expected to be used, and no exceptional provision is made for the case of a Bridge not being able to allocate an SPSourceID. If an SPSourceID is not available, frames for VLANs supported by SPBM mode are discarded.

The pool of SPVIDs are those available for allocation and reserved in the MST Configuration Table. The MCID (13.8) communicated in SPT BPDUs ensures that each Bridge in an SPT Region has agreed to the same pool of SPVIDs. A quantity of 400 SPVIDs are pre-configured for auto allocation (13.8) for small SPT networks running SPBV. Additional SPVID allocations can be made out of the remaining free VIDs. An MST Configuration Table change that extends the available SPVID pool does not disturb existing allocations, but will affect the MCID—so the connectivity between adjacent Bridges will revert to the CST representing a region boundary, unless the procedures for hitless migration of MCIDs using Auxiliary MCID (27.4.1) are followed. If a Bridge is added to a region or a new SPBV VLAN configured and there are not enough SPVIDs to satisfy the demand, any SPBV VLAN that does not have a full allocation of SPVIDs falls back to CST operation using its Base VID. When enough SPVIDs become available, either by being freed from other SPBV VLANs or by increasing the size of the SPVID pool, and an SPBV VLAN obtains a full allocation of SPVIDs it advances to SPBV operation using the SPVID set. During periods when there are insufficient SPVIDs to satisfy all SPBV VLANs, Bridges that have successfully obtained allocations of SPVIDs to SPBV VLANs must maintain them to ensure stable behavior.

27.11 Allocation of VIDs to FIDs

The allocation of SPVIDs to FIDs (8.8.8) for SPBV is a local decision, subject to the following constraints:

a) All SPVIDs (if any) supporting a given VLAN (identified by Base VID V_1, say) shall be allocated to the same FID (F_{SV1}, say).
b) SPVIDs shall be allocated to FIDs (F_{SV1}, F_{SV2}, ..) that are different from those allocated to any VLAN's Base VID (F_{V1}, F_{VN} ..).
c) VLANs supported by different SPT Sets always use different FIDs (both for SPBV and SPBM modes).
d) If the VID to FID allocation table (8.8.8) has been configured to allocate two different Base VIDs to different FIDs (F_{V1}, F_{V2}), then the SPVIDs used to support each of the VLANs identified by those Base VIDs shall be allocated to different FIDs (F_{SV1} != F_{SV2}).
e) If the VID to FID allocation table (8.8.8) configuration allocates two different Base VIDs to the same FID ($F_{V3} = F_{V4}$), then the SPVIDs shall also be allocated to the same FID ($F_{SV3} = F_{SV4}$). This is shared VLANs where two or more VLANs can share the same topology.
f) SPVIDs allocated to FID in this manner do not show up in the MCID as changed.

NOTE 1—Frames for VLANs supported by SPBM mode are always assigned to an SPT Set within an SPT Region, never to the IST, and are always identified by each VLAN's Base VID.

NOTE 2—Constraint (b) allows the active topology for any SPBV supported VLAN to be changed from the IST to an SPT Set without requiring topology change signaling.

These constraints, and the fact that the MST Configuration Table's entries for VLANs supported by SPB are not configured directly but are a consequence of configuring the relationship between Base VIDs and FIDs (8.8.8) and between FIDs and MSTIDs (8.9.3), also ensure the following:

g) SPT Bridges using SPBV and SPBM modes always use different FIDs, so SPBV learning cannot disrupt SPBM operation.
h) VLANs with shared learning constraints (expressed by allocation of a common FID) are assigned to the same SPT Set.

If all the MAC addresses for a VLAN supported by SPBM mode are those of BCBs and BEBs, then the use of different FIDs for B-VLANs supported by the same SPT Set can seem unnecessary. However, the constraints could support additional capabilities and shall be followed.

27.12 SPBV SPVID translation

An SPT Bridge Port that is a Boundary Port (13.12) translates, on both ingress and egress, the VID assigned to a VLAN that is supported by SPBV. On reception, the Boundary Port uses the VID Translation Table (6.9) to translate the Base VID received in the tag to the SPVID for the SPT rooted at that Bridge. On transmission, the Boundary Port uses the Egress VID Translation Table (6.9) to map all of the SPVIDs for that VLAN to one Base VID. The Boundary Port's VID Translation Table is also configured to prevent any local VID from being translated to a relay VID within the SPVID range.

NOTE 1—One way to prevent local VIDs within the SPVID range from being translated to relay VIDs in the SPVID range is to change the default relay VID value for these entries to the reserved value 0xFFF, which would cause these frames to be discarded.

If it has not been possible to allocate SPVIDs to support a given VLAN, no translation is performed and the frame is carried on the IST within the region using the unmodified Base VID.

If a Boundary Port's untagged or priority tagged frames belong to a VLAN supported by SPBV, the PVID for that port is set to the SPVID for the SPT rooted at that Bridge, and the port should belong to the untagged set for each of the SPVIDs for that VLAN.

Frames received on ports internal to the region are not translated, whether they carry SPVIDs or Base VIDs.

NOTE 2—A frame within any Bridge within an SPT Region is considered as being forwarded within that region. Consequently a frame that is forwarded between two Designated Ports at the boundary of a region can have its VID translated on reception, from the VLAN's Base VID to the SPVID for the VLAN and SPT rooted at the Bridge, and on transmission, back to the Base VID. Translation is not dependent on forwarding, so the frame could have been equally forwarded through a port within the region.

27.13 VLAN topology management

An SPT Bridge using SPBV mode uses Dynamic VLAN Registration entries, for each VLAN it supports, to create a VLAN topology that is the pruned subset of the active topology that connects participants in that VLAN. The VLAN registration entries thus serve to prevent both loops and unnecessary flooding of frames through Bridge Ports and LANs that cannot provide connectivity to their destinations.

Each SPT Bridge uses ISIS-SPB with the information calculated for the CIST and each SPT (27.6, 27.7, 27.8), and the following information from each Bridge in the SPT Domain with one or more Boundary Ports:

a) VLAN membership registration for each VLAN registered on a Boundary Port, subject to the registration controls defined for MVRP (11.2.3.2.3).

For each of its Bridge Ports that is not a Boundary Port, and for each VLAN supported by SPBV mode, the SPT Bridge computes the following potential values of control in VLAN registration entries:

b) Forwarded or Filtered, for the IST, for each port that is a Root Port or a Designated Port
c) Filtered, for the IST, for each port that is an Alternate Port or Backup Port
d) Forwarded or Filtered, for each SPT, for each port that is a Designated Port
e) Forwarded, for each SPT, for each port that is a Root Port
f) Filtered, for each SPT, for each port that is an Alternate Port or Backup Port

The potential control element for the CIST specifies that frames for the VLAN are to be Forwarded, if the port provides CIST connectivity to a Boundary Port that has registered the VLAN. Similarly the potential control element for an SPT Designated Port specifies Forwarded if that port provides the shortest path to a Bridge with a Boundary Port that has registered the VLAN, either directly (if that Bridge is in the same region) or via a Boundary Port that provides CST connectivity to the Bridge in another region in the domain.

VLAN Registration Entries support ingress filtering, so the potential control element always specifies Forwarded for each SPT's Root Port, thus supporting Open Host Groups (10.10.1). However, an SPVID is only allocated (27.10), to support a given VLAN over a given SPT, if frames for that VLAN can enter the SPT Region at the root of that SPT, so the potential control element might not be used.

Each SPT Bridge creates Dynamic VLAN Registration Entries using the potential control elements and the Port State variable forward (27.9) for each tree for each VLAN supported by SPBV as follows:

g) An entry for the Base VID specifies Registered for a port if:
   1) forward is True for the IST for the port and
   2) the potential control element for the port for the IST and the VLAN specifies Forwarded

   and specifies Not Registered for the port otherwise.

h) An entry for each SPVID specifies Registered for a port if:
   1) forward is True for the port for the SPT identified by the SPVID and
   2) the potential control element for the port for the SPT and the VLAN specifies Forwarded

   and specifies Not Registered for the port otherwise.

These Dynamic VLAN Registration control elements for each of the SPT Bridge's ports are subject to restrictions imposed by Static VLAN Registration Entries. Static VLAN Registration Entries shall not be administratively created for any SPVID, so the controls applied to shortest path forwarding are solely those determined at the boundaries of each SPT Region.

VLAN topology management for an SPT Bridge using SPBV, as specified in this subclause (27.13), makes use of Static and Dynamic VLAN Registration Entries that can be used with MVRP. However, their use in this clause is independent of whether MVRP is implemented or used, and does not require the Bridges in an SPT Domain to agree on its use. If MVRP is implemented and used on Boundary Ports, then MVRPDUs are transmitted and received on those ports (as permitted by the controls specified for MVRP) to exchange registration information with Bridges or end stations outside the SPT Domain.

Since SPBM mode only forwards frames whose destination and source addresses are known to ISIS-SPB, the filtering entries installed for these addresses can be used to control all forwarding for each SPBM supported VLAN. SPBM mode creates a Dynamic VLAN Registration Entry for the VLAN used by the SPT Bridge. Operators should not create Static VLAN Registration Entries for the VLAN used by SPBM mode.

27.14 Individual addresses and SPBM

Each SPT Bridge that supports SPBM mode may be configured to use loop prevention (6.5.4.1) and/or loop mitigation (6.5.4.2) for unicast frames assigned to VLANs supported by the SPT Bridge. Loop prevention is always used for multicast frames. Both loop prevention and loop mitigation use Dynamic Filtering Entries for individual MAC addresses for each VLAN supported by SPBM mode. These filtering entries serve both to implement ingress checking, effectively assigning each received frame to an SPT and ensuring that the frame is only forwarded if received on the Root Port of that tree, and to implement egress checking, ensuring that the frame is only forwarded through the port providing the shortest path to its destination.

SPBM mode uses VLAN membership configuration information distributed by ISIS-SPB to reduce the number of individual address filtering entries, i.e., {VID, Individual MAC Address} tuples that need to be made in each SPT Bridge. Entries for a given VID are made only for ports that are in the pruned subset of the active topology that connects participants in the VLAN with that Base VID.

NOTE—The reduction in individual address entries is most effective in very large SPBM-capable networks, using hundreds (or thousands) of Bridges, and hundreds of B-VLANs each covering a small subset of the Bridges, each subset supporting a number of backbone service instances. Using a large number of B-VLANs in such a network could significantly reduce the scope of the control flows used to create and maintain backbone service instances.

27.14.1 Loop mitigation

If loop mitigation is selected, each SPT Bridge can create or modify an individual address filtering entry (for a given VLAN) once the calculation of the SPT rooted at that Bridge (and in the SPT Set for that VLAN) has associated the address with one of the Bridge's ports, subject to satisfying constraints that prevent multicast loops. These constraints are those that govern the Port State transition of a Root Port to Forwarding (i.e., on setting the Port State variable forward true for SPT's Root Port, as specified in Clause 13). This subclause (27.14.1) specifies a sufficient, though not necessary way to meet those constraints. If any discrepancy exists between this summary and the Clause 13 specification, the latter takes precedence.

The Port Role Transition machine ensures that there are no disputes with the adjacent Bridge(s) with respect to the active topology, such as might arise from partial or one-way connectivity (13.21). Otherwise, the Dynamic Filtering Entry can be created or modified provided:

a) The entry was previously unused, or the operation of changing the entry ensures that no two ports can be receiving frames from or sending frames to the same {VID, Individual Address} tuple at the same time; and
b) The Static Filtering Entries that limit the propagation of the SPBM SPT-specific group addresses for that SPT have been deleted or specify Filter on all ports (27.15).

NOTE—Where a large number of SPT-specific group addresses are used, the effectiveness of loop mitigation as a strategy (for more rapidly restoring unicast connectivity after a component failure than might be achieved by using loop prevention) depends on the ability of the implementation to rapidly suspend multicast connectivity, as required by (b) above, possibly by distinguishing unicast and multicast forwarding.

27.14.2 Loop prevention

If loop prevention is selected, Dynamic Filtering Entries for individual MAC addresses for VLANs supported by SPBM mode reflect SPT Port States for both Root Ports and Designated Ports, for different SPTs in the SPT Set for each VLAN. The state machines specified in Clause 13 attempt to minimize the changes to filtering entries necessary following a network component failure by identifying conditions when the change in active topology constitutes a loop-free alternative. Otherwise, Dynamic Filtering Entries are removed as necessary as part of making the forwarding variable False, so that an Agreement Digest can be transmitted to adjacent Bridges and full connectivity restored.

NOTE—The Clause 13 state machines specify necessary conditions for creating new connectivity. These conditions can be satisfied in a number of ways, by processes that can execute in parallel in adjacent Bridges and in the same Bridge. The most effective way (time taken, resource expended) is implementation dependent, and is not specified as a set of fixed steps. For example, Static VLAN Registration Entries (or an implementation-dependent equivalent) could be used to disable forwarding to allow a fresh Agreement Digest to be sent at the earliest opportunity. Alternatively, where SPBM mode uses a large number of SPT-specific group MAC addresses to support many backbone service instances between rather fewer SPT Bridges, removing (or disabling) Dynamic Filtering Entries for individual addresses entries being used as an ingress check may be more expedient.

27.15 SPBM group addressing

When a B-VLAN is supported by an SPT Bridge using SPBM, the individual destination and source MAC addresses of each frame are those used by entities within SPT Bridges or within systems that include an SPT Bridge Component, such as BEBs (Clause 3, Clause 25). SPBM mode assigns group addresses of local significance to the SPT Domain for use by those entities. For symmetric ECT Algorithms (28.8), group addresses are assigned to source rooted trees and include an SPSourceID (27.10). Taken together each frame's B-VID and SPSourceID identify the source rooted SPT used to forward the frame. For the ECMP ECT Algorithm (44.1.2), group addresses may be assigned to one of 16 source rooted trees per bridge or to one of 16 shared trees. Group addresses assigned to source rooted trees include an SPSourceID and I-SID, and the I-SID may be associated with a Tie-Break Mask. Together the B-VID, SPSourceID, and Tie-Break Mask identify the source rooted SPT used to forward the frame. Group addresses assigned to a shared tree include the Tie-Break Mask used in root node selection, and the I-SID. The B-VID and Tie-Break Mask

together identify a particular shared tree used to forward the frame. In all cases ISIS-SPB's knowledge of the addressed group and its assigned tree allows it to create a MAC Address Registration Entry (8.8.4) for the address, restricting propagation to the pruned subset of the tree that reaches the group's members.

In particular, a distinct group MAC address is assigned to each VIP (Clause 3) for use as the B-DA of the multicast frames that it transmits into an SPT Domain. Each VIP supports a single backbone service instance, so the B-DA identifies the I–SID for each customer frame that is multicast and its transmission is confined to LANs providing connectivity between BEBs supporting that service instance.

Figure 27-2 illustrates the general format of SPBM group MAC addresses. The octet and bit ordering and identification conventions used in this figure follow those of Figure 10 of IEEE Std 802-2014 [B5]. The conventions used to encode parameters with numeric values, such as the SPSourceID or I–SID, are those used elsewhere in this standard (14.1.1): the number is encoded as an unsigned binary numeral with bit positions in lower octet numbers having more significance. The least significant and the next to least significant bits of the first octet of the address, the Individual/Group and Universally/Locally administered bits, are both set denoting a locally administered group address. The two next most significant bits compose an SPBM address type, permitting alternative uses of the remaining bits of the address.

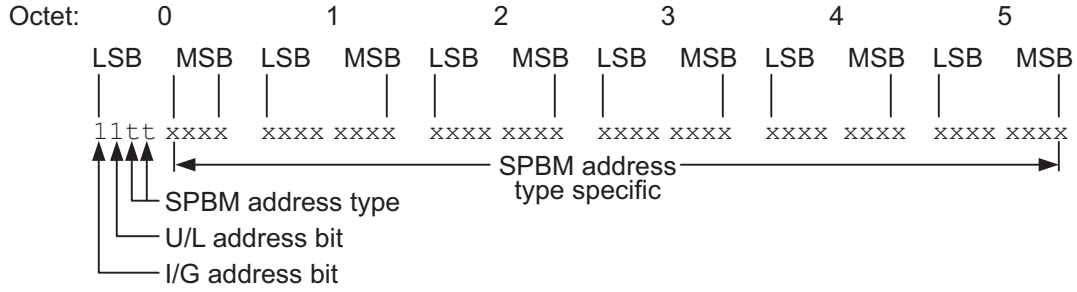

Figure 27-2—SPBM group MAC address—general format

This standard encodes the I–SID in the last three octets, and the value 0 or 1 in the address type field. Other values (2 and 3) are reserved for future standardization. The address format for group addresses assigned to a source rooted SPT is shown in Figure 27-3. In this format the SPSourceID is encoded in the first three octets.

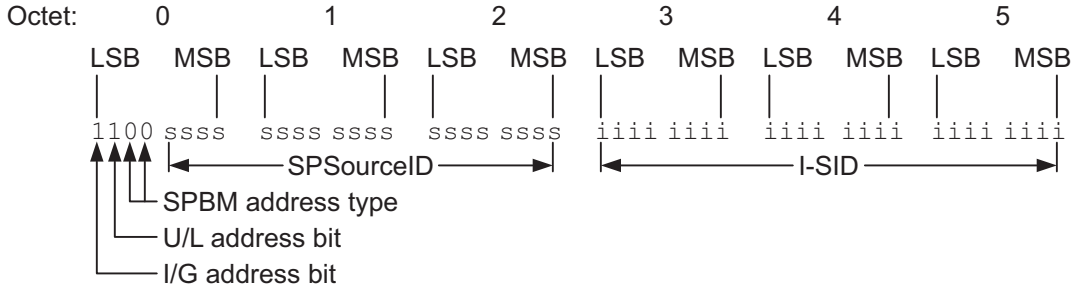

Figure 27-3—SPBM group MAC addresses—source rooted SPT

Figure 27-4 shows the format for group addresses assigned to a shared tree. Four bits of octet 2 are used to encode the Tie-Break Mask identifying the shared tree. If the same group address were to be used in two shared trees, forwarding loops could be created. The Tie-Break Mask is included in the group address so that the addresses used in different shared trees are distinct and forwarding loops are not created. The remaining bits are set to zero, leaving a substantial portion of the SPBM type 1 address space available for future use.

The use of locally assigned group MAC addresses by SPBM mode does not affect the use of the same or different group MAC addresses for other VLANs. In addition to creating and managing the required FDB entries for each specific group address (GA_{SPBM}) for any given Base VID (V_{SPBM}, say) that identifies an SPBM mode supported VLAN, an SPT Bridge using SPBM mode also manages the following entries:

— If the FDB contains a static entry specifying Forward (for any Bridge Port) for the wildcard VID and any specific group MAC address not required by this subclause (27.15) then an entry specifying Filter (for all Bridge Ports) is also created for that group address and each Base VID supported by SPBM mode.

— A Static Filtering Entry for All Group Addresses (for which no more specific Static Filtering Entry exists, (8.8.1) is created for each Base VID supported by SPBM mode, specifying that those addresses are to be filtered.

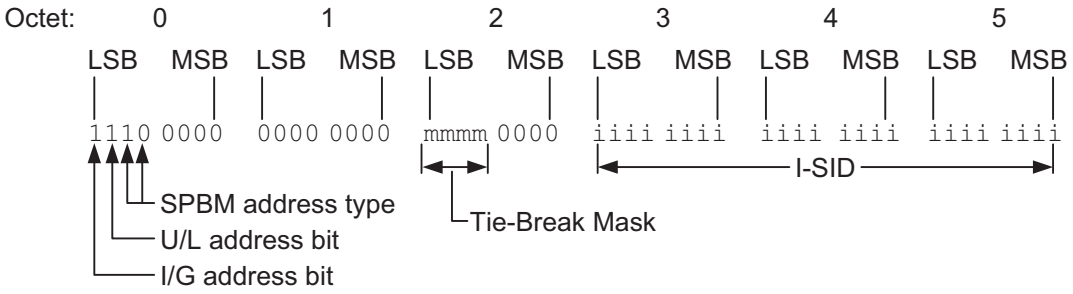

Figure 27-4—SPBM group MAC addresses—shared tree

27.16 Backbone service instance topology management

An SPT Bridge using SPBM mode uses Dynamic Filtering Entries to explicitly permit unicast communication between stations, thus restricting that communication to the shortest path between those stations. SPBM mode also uses Static Filtering Entries, for each VLAN it supports, to create a multicast topology that is the pruned subset of the active topology that connects BEBs supporting the same backbone service instance using that VLAN.

Each SPT Bridge uses ISIS-SPB with the information calculated for the CIST and each SPT (27.6, 27.7, 27.8), and the following information from each BEB in the SPT Domain:

a) I-SID membership registration for each VLAN supported by SPBM mode

For each of its Bridge Ports, for each I-SID and each SPT supporting the VLAN supporting that I-SID, the SPT Bridge computes the potential filtering control element values, Forward or Filter, for each port that is a Designated Port or Root Port. The potential control element specifies Forwarded if that port provides the shortest path to a BEB that has registered the VLAN, either directly (if that Bridge is in the same region) or via a Boundary Port (if the Bridge is in another region in the domain). A value of Filter is associated with each port that is an Alternate Port or Backup Port for the SPT.

The SPT Bridge creates a Static Filtering Entry for the VLAN's B-VID and SPBM Group Address (27.15) for the I-SID and SPT, with a control element that specifies Forward if both the potential control element specifies Forward and the Port State variable forward (27.9) is True for the SPT for the port.

27.17 Equal cost shortest paths, ECTs, and load spreading

There can be several equal cost shortest paths between any given pair of Bridges, and the paths used by the SPTs in a given SPT Set are required to be symmetric (13.1), so the local tie-breaker [the lowest ISIS Local Circuit ID on the Bridge with the best (numerically least) SPB System Identifier (Clause 3)] is only used to select between links providing alternative connectivity between immediately adjacent Bridges. Equal cost tie breaking between paths that traverse different sets of Bridges is performed by calculating a unique identifier for each path that is independent of order used to compute trees. See 28.5 for a description of the Algorithm and the tie breakers.

The capability to support multiple VLANs using different ECTs allows a network administrator to choose different equal cost paths for different services by assigning services to selected VLANs. ECMP (Clause 44) provides the capability to spread load across equal cost shortest paths using a single SPBM VID.

A set of ECT Algorithms (28.8) is specified, each using a different tie breaker. The tie-breaking rules have been selected to provide a reasonable probability that different ECT Algorithms will choose different paths from a set of equal cost paths. ECT path selection can be controlled by selection of ECT Algorithm and by adjustment of Bridge Priorities.

SPB makes use of all nodes in the SPT region for forwarding.

27.18 Connectivity Fault Management for SPBM

Connectivity Fault Management (CFM) as specified in Clause 18 through Clause 22 provides capabilities useful in detecting, isolating, and reporting connectivity faults in VID-based service instances, backbone service instances, and TESIs. As with PBB-TE, SPBM disables flooding of frames with unknown destination address. This and other changes in behavior with SPBM require some modification to VLAN CFM functions. The modifications related to SPBM are summarized here.

In particular, this subclause summarizes SPBM considerations related to the following:

a) SPBM MA types (27.18.1)
b) SPBM MEP placement in a Bridge Port (27.18.2)
c) SPBM MIP placement in a Bridge Port (27.18.3)
d) SPBM modifications of the CFM protocols (27.18.4)

27.18.1 SPBM MA types

SPBM CFM uses three types of MA: SPBM VID MAs, SPBM path MAs, and SPBM group MAs.

An SPBM VID MA operates like a VLAN MA. For example, SPBM MEPs multicast CCM frames to all other MEPs and expect to receive CCM frames from all other MEPs in an SPBM VID MA. There are minor differences from VLAN MAs, primarily in the destination addresses used for CFM frames. SPBM VID MAs can be used to monitor and diagnose SPBM connectivity.

SPBM specifies two MA types for testing forwarding state installed by ISIS-SPB for specific addresses. In SPBM path MA CCMs are used to test the path for an individual destination MAC address between a pair of endpoints. This type of MA has only two MEPs, at two SPT Region boundary ports. An SPBM path MA is identified by a TE-SID comprising an ESP in each direction between the two endpoints. In an SPBM group MA CCMs are used to test a set of multicast trees used by a backbone service instance. This type of MA has multiple MEPs, each located at a CBP supporting the backbone service instance whose multicast trees are to be tested. An SPBM group MA is identified by the I-SID whose multicast trees it tests. The path taken by CCM frames depends on the current state of the network (i.e., paths are subject to rerouting triggered by

topology changes). A CCM defect detected by an SPBM path MA or SPBM group MA may indicate a problem with the forwarding state for the MAC addresses being tested. This standard does not specify the mechanisms that would be necessary to support Loopback and Linktrace on an SPBM path MA or SPBM group MA since full Loopback and Linktrace coverage can be provided by an SPBM VID MA. Therefore, there are no MHFs associated with an SPBM path MA or SPBM group MA.

27.18.2 SPBM MEP placement in a Bridge Port

SPBM MEPs are always Up MEPs and can only be placed on CBPs as these correspond to the demarcation points of the SPT Region. The SPBM MEPs are placed between the Frame filtering entity (8.6.3) and the Port filtering entities (8.6.1, 8.6.2, and 8.6.4) in the VID space identified by the EISS Multiplex Entity (6.17). An SPBM VID MEP is placed in the same location as a VLAN MEP as shown in Figure 27-5.

Since SPBM path MEPs and SPBM group MEPs must only see traffic using specific addresses, these MEPs need to be further differentiated by the TESI Multiplex Entity (6.19). This locates an SPBM path MEP or SPBM group MEP so that it receives CCMs only from the other MEPs in its MA. Figure 27-5 also shows an example of an SPBM path MEP and SPBM group MEP on a CBP.

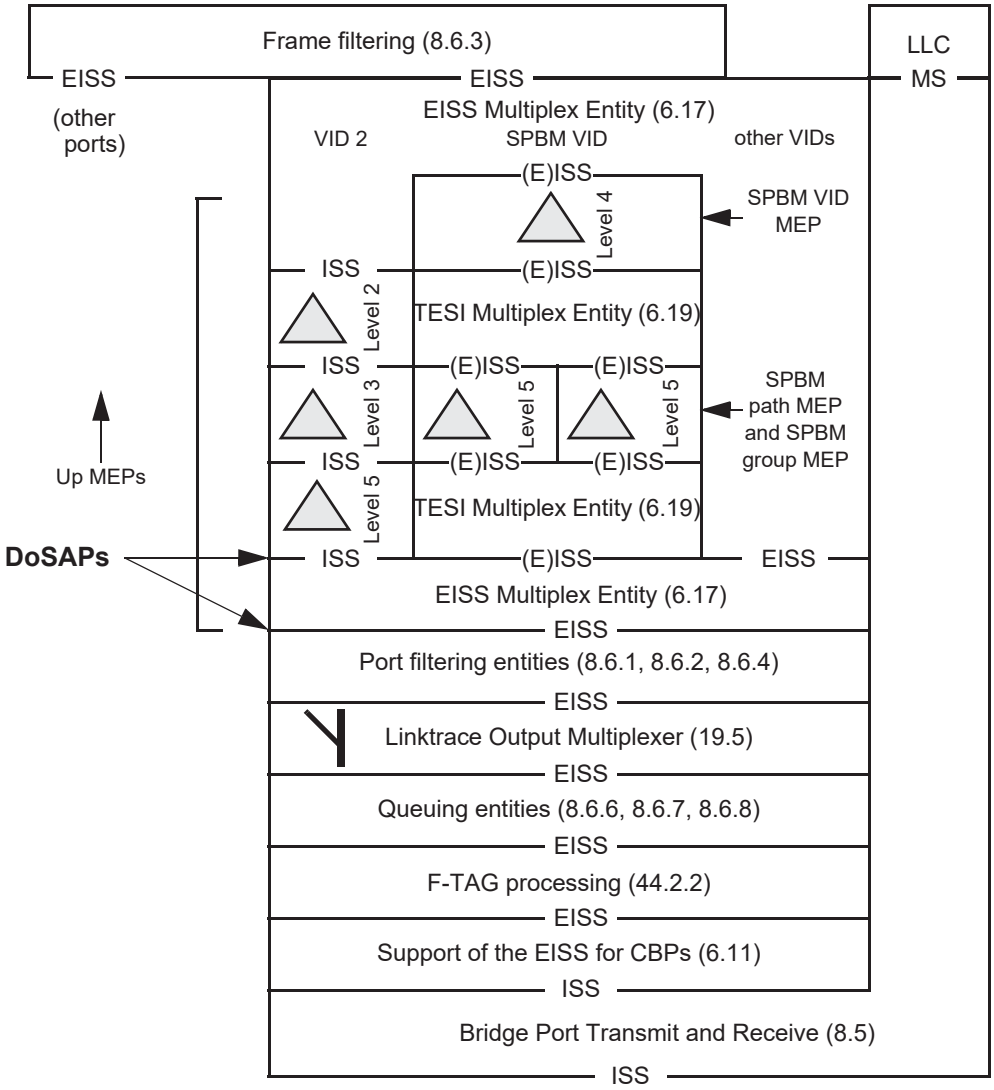

Figure 27-5—SPBM MEP placement in a CBP

27.18.3 SPBM MIP placement in a Bridge Port

SPBM MIP creation is based on the algorithm described in 22.2.3. SPBM MIPs are created per identified VIDs on PNPs. Figure 22-9 depicts an example of a pair of SPBM MHFs on a PNP.

27.18.4 SPBM modifications of the CFM protocols

27.18.4.1 Continuity Check protocol in an SPBM MA

The Continuity Check protocol is described in 20.1, and the corresponding state machines are presented in Clause 20. The modifications required to realize SPBM MAs include the following:

a) In the case of an SPBM VID MEP, the destination_address parameter is set to the group MAC address for the SPBM default I-SID (Table 9-3) for the Bridge on which the MEP is configured. In the case of an SPBM path MEP, the destination_address parameter is set to the MAC address indicated by the ESP-DA field of the ESP having in its ESP-SA field the MAC address of the MEP. In the case of an SPBM group MEP the destination_address parameter is set to the SPBM group MAC address assigned to the source MEP's CBP for the SPBM group MA's I-SID [item a) in 20.11.1].
b) In the case of ECMP with flow filtering, the flow_hash and time_to_live parameters are set [item e) in 20.11.1].

All other Continuity Check processes are the same as those for a VID-based MA.

27.18.4.2 Loopback protocol in an SPBM MA

The Loopback protocol is described in 20.2 and the corresponding state machines in Clause 20. The modifications required to realize the SPBM MA are summarized below:

a) To enable MIPs to selectively intercept LBMs that are targeting them, the PBB-TE MIP TLV (21.7.5) is inserted as the first TLV [item g) in 20.31.1] in an LBM. The format of the PBB-TE MIP TLV is described in 21.7.5 and is constructed as follows:
    1) The MIP MAC address field contains the MAC address of the MIP to which the LBM is targeted [item b) in 12.14.7.3.2].
    2) The Reverse VID field and Reverse MAC field are not used in SPBM.
b) An SPBM MHF forwards all received LBMs except those carrying a PBB-TE MIP TLV containing in their MIP MAC address field the MAC address of the MIP associated with that SPBM MHF [item f) in 20.28.1].
c) In the case of ECMP with flow filtering, the flow_hash and time_to_live parameters are set [item d) in 20.31.1].

NOTE—The MIP MAC address for an LBM does not have to be advertised by ISIS-SPB since it is only used locally to match the value provided in a PPB-TE MIP TLV.

All other Loopback processes are the same as those for a VID-based MA.

27.18.4.3 Linktrace protocol in an SPBM MA

The Linktrace protocol is described in 20.3 and the corresponding state machines in Clause 20. The modifications required to realize the SPBM MA are summarized as follows:

a) The LTMs transmitted by a MEP associated with an SPBM MA use as the destination_address parameter the MAC address indicated in the LTM management request [item c) in 12.14.7.4.2].
b) No special destination_address validation tests are performed by the ProcessLTM() procedure in the case of SPBM MAs [item c) in 20.47.1].

c) To identify a possible egress port, an SPBM MIP queries the FDB of its associated bridge using the destination_address and the vlan_identifier of the LTM as the parameters for the lookup (20.47.1.2). In the case of ECMP with flow filtering, the flow_hash value of the LTM is also used for the lookup, if required. For group addresses, LTMs can be further forwarded by SPBM MIPs even if the lookup identifies more than one Egress port.

d) In the case of ECMP with flow filtering, the flow_hash and time_to_live parameters are set [item d) in 20.42.1].

All other Linktrace processes are the same as those for a VID-based MA.

27.19 Using SPBV and SPBM modes

This subclause provides one example topology of SPT Bridges using SPBV mode and one example topology of SPT Bridges using SPBM mode.

27.19.1 Shortest Path Bridging—VID

The primary advantage SPT Bridges operating in SPBV mode bring over spanning tree protocols is the more flexible shortest path forwarding. SPBV accomplishes this by using SPVIDs and VID translation (6.9) at SPT Region boundaries. All traffic within an SPT Region always takes a shortest path. Loops are prevented by never allowing traffic to be accepted on a non symmetric shortest path and enforced with loop prevention (13.17, 6.5.4.1).

An example campus network using SPBV is illustrated by Figure 27-6. The SPT Region contains eight SPT Bridges with two RST Bridges connected to the SPT Region. All VLANs within the SPT Region are supported by the SPT Bridges. The dashed lines represent the SPT for the SPVID of a Base VID (VID10) for which Access Bridge 1 is source (root of the SPT). The solid lines to the RST Bridges indicates spanning tree forwarding. VID translation from and to the respective SPVIDs occurs on the region boundary ports SPT Bridge D port 5 and SPT Bridge E port 3. SPT forwarding makes better use of a mesh network; however, it only will use a single path per Base VID. For example the Bridge D port 2 to Bridge B port 4 link is not used by access Bridge 1 because the ECT Algorithm has chosen paths through Bridge C. If another VLAN is supported in this network the recommendation is to use a different ECT Algorithm that could choose D-B over C-B by using an appropriate tie breaker (28.8).

ISIS-SPB uses SPB Hellos to establish adjacencies within the SPT region and BPDUs to establish peering with RST Bridges. BPDUs from legacy Bridges L1 and L2 will indicate that they are able to use RSTP. Therefore, RSTP would be enabled and SPB Hello would be transmitted periodically but dropped. The ports connected to the legacy Bridges are enabled and block according to RSTP logic.

SPT Bridges using SPBV mode use the same principles as MSTP to form a logical Bridge with a CIST root port on Bridge A, which has the best (numerically least) Bridge Identifier in the SPT Region. The CIST in Figure 27-6 is a spanning tree rooted on Bridge A (not illustrated).

a) The eight Bridges in the SPT Region have the same MCID (13.8) or Auxiliary MCID (28.9).

b) The CIST is computed in the SPT Region and maintains the spanning tree root costs (13.17).

c) SPT BPDUs are exchanged by the SPT Bridges within the SPT Region (13.17).

d) VLANs identified by other than the Base VIDs are supported by the CIST (13.17).

Legacy Bridges L1 and L2 can be aware of the SPB operation of Bridges but they only support RSTP and interface to the aggregation Bridges D and E using RST BPDUs. L1 and L2 learn from the received BPDUs that aggregation Bridge A is the Designated Bridge for VLAN 10 while a Bridge somewhere above the SPT region is the CIST Root for the network. Aggregation Bridge D receives traffic from L1 but uses an SPVID and the corresponding SPT from D to reach all nodes within the region and beyond. Normal learning of MAC addresses occurs.

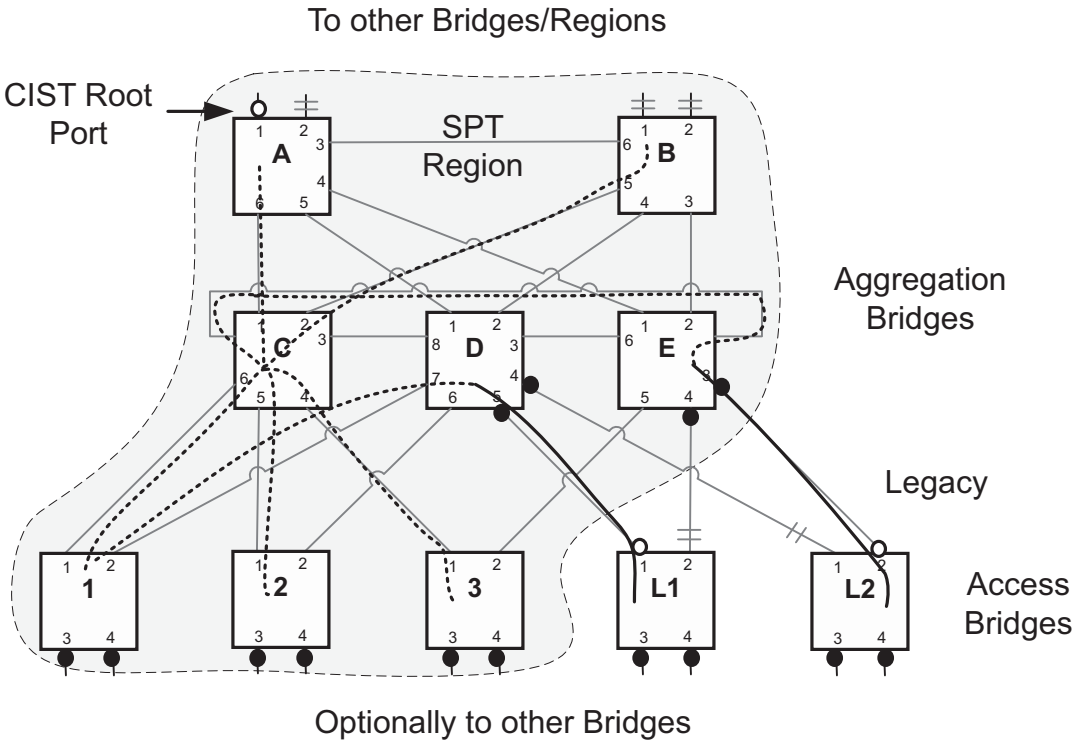

Figure 27-6—SPBV campus network example

Dynamic VLAN Registration capabilities are supported natively for Base VIDs by utilizing the link state to auto enable forwarding on intermediate Bridges. Referring to Figure 27-6, if access Bridge 1 and aggregation Bridge A were the only Bridges with VID 10 registered on their boundary ports forwarding would automatically be setup on aggregation Bridge C to complete the data path between Bridge 1 and Bridge A. Only Bridges configured with the Base VID, Bridge 1 and Bridge A require SPVIDs. MVRP for other VLANs is supported on the CIST.

MAC Address Registration (8.8.4) is supported for the Base VIDs as outlined in 28.10. Group addresses for Base VIDs are distributed in ISIS-SPB. At the region boundaries MMRP is required to propagate registration to and from the SPT Region.

Since the SPT Region follows very similar design rules as the MST Region, RSTP and STP interwork with both. SPB interworks with MSTP and other SPT Regions with MSTP.

27.19.2 Shortest Path Bridging—MAC

An example SPT Bridge network using SPBM mode is illustrated by Figure 27-7. The SPBM mode example network is divided into two major areas: the customer equipment area, which is owned by the “customer” and is connected to the SPT BEBs using C-tagged or S-tagged interfaces; and the SPT Region, which is owned by the backbone provider and interconnects to the customer equipment and possibly to other SPT Bridges. There is no visibility of either backbone topology or B-MAC addresses outside the SPT Region, and consequently connections to other SPB or PBB areas will be identical to those to customer equipment. While this is primarily leveraging the capabilities of the PBBN the emphasis is that the separation of the address spaces proved by the PBB encapsulation provided useful capabilities of scaling even larger enterprise or data center networks (DCNs) where bridging and delivery of optimized unicast and multicast frames on an S-VLAN basis is desired.

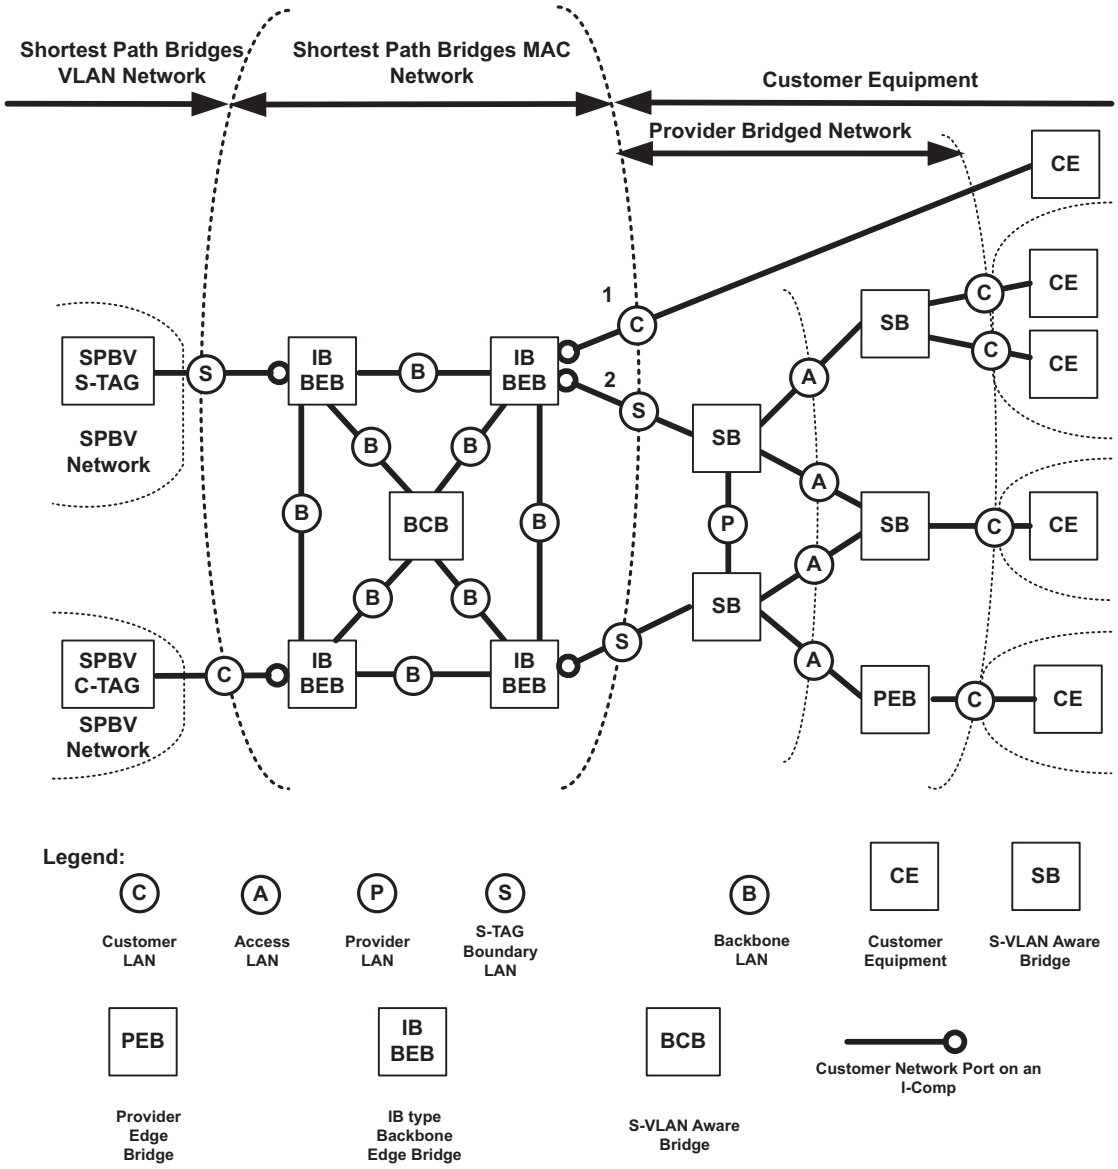

Figure 27-7—SPT Bridge Network using SPBM example

The interface between an IB BEB and a customer Bridge is a CNP of an I-Component as specified in 6.10. The interfaces between BEBs and BCBs and between BCBs and other BCBs are PNPs. In Figure 27-7, these interfaces are over LANs labeled S and B. All exterior interfaces from a SPT Bridge network using SPBM mode are over S, or C LANs; whereas all interior interfaces within a SPT Bridge network support appropriate segments of SPB SPTs, each set of which is identified by one Base VID per forwarding topology. Each individual SPT within a set is identified by the B-MAC address of its source Bridge. The S and C VLANs (exterior interfaces) are at the boundary between the SPT Bridge network and the attached customer networks.

Within the network example, BEBs, BCBs, and the SPTs for each Base VID are secured so that only the network administrator operating the SPT Bridge network can manage the reception, transmission, and relay of frames between BEBs and BCBs. The arbitrary physical network topology of the SPT Bridge network and the connectivity that it provides to support segregated instances of the MAC Service is designed and managed by the network administrator to meet bandwidth and service availability requirements at the CBPs

and PIPs. Application of the service instance ingress and egress rules at these Ports in support of service instance selection and identification ensures that frames cannot be transmitted or received on any backbone service instance by any customer's equipment without prior agreement with the administrator of the SPT Bridge network.

The active topology of the SPT Bridge network is separated from the active topology of the customer equipment area. This is accomplished by isolating the BPDUs for each customer network from the SPT Bridge network at the BEBs that surround the perimeter of the SPT Region. The ISIS-SPB LSPs and SPT BPDUs, that support the active topology of the SPT Bridge network, are only exchanged on PNPs and hence are not leaked into the customer bridged area.

B-MAC addresses are used to identify the destination BEB's PIP. These B-MAC addresses are advertised by each BEB to all other BEBs and BCBs in the SPT Bridge area in LSPs as part of the IS-IS routing exchanges. I-SID instances associated with each PIP are also advertised using the same mechanism. To perform the encapsulation and de-encapsulation of service frames, BEBs use the connection identifier stored in the FDB (8.8) to correlate C-MAC addresses to B-MAC addresses. At startup, after convergence of ISIS-SPB, the BEBs are aware of the location of B-MAC addresses in the topology, but have not learned the C-MAC addresses yet. When the C-MAC address is unknown, the BEB encapsulates the service frames using an SPBM Group address, which is analogous to the Backbone Service Instance Group address (26.4). This address is then multicast to the set of registered receivers that are those BEBs where that I-SID has been configured. The same holds true for the service frames having a group or broadcast destination address. An individual B-DA is used for forwarding unknown or group frames when the service is point-to-point and where the far end individual address is known. C-MAC addresses are learned by the provider BEB against the B-MAC address associated with the service interface on the BEB that sourced them (see Clause 25).

27.20 Security considerations

This clause contains no exceptional provisions for securing the operation of ISIS-SPB. ISIS has a number of optional capabilities that may be utilized. For example, ISIS-SPB does not prevent the use of the IS-IS Authentication TLV. If stronger security is required, IEEE 802.1AE™ MAC Security should be deployed on all SPT Bridge Ports, and the configuration of the controls provided by this standard to regulate the acceptance of spanning tree protocol information [e.g., restrictedRole and restrictedTcn (13.27.64, 13.27.65)] should be set to reflect the degree of trust (i.e., authorization) accorded to the mutually authenticated securely communicating peer Bridges. SPT BPDUs include a flag that indicates that the attached LAN is not considered to be a part of the transmitting Bridge's SPT Region: this avoids one way participation in a region if one Bridge considers the authorization of another inadequate. Use of MAC Security in this way can ensure that only authenticated and authorized (i.e., trusted) Bridges participate in a region, as well as preventing unauthorized transmission of ISIS-SPB information or user data on LANs within the region.

28. ISIS-SPB Link State Protocol

Intermediate System to Intermediate System (IS-IS) is the link state routing protocol used for SPB (Clause 27). IS-IS is easily extended to carry the required Ethernet addresses, VLAN and Service membership information introduced by SPB. IS-IS is defined in ISO/IEC 10589:2002. When used for SPB, IS-IS has no IP dependencies. IS-IS also supports Multi-Topology (MT) and logical instances for easy virtualization of the link state protocol. This subclause specifies extensions to IS-IS for SPB. IS-IS extended for SPB will be referred to as *ISIS-SPB*. The SPB extensions are additive to IS-IS and do not preclude the IS-IS protocol being used for other purposes at the same time.

In VLANs that are configured to use SPB, ISIS-SPB controls forwarding (Clause 8) of individual and group addressed MAC frames. The Agreement Protocol (13.17), utilizes the ISIS-SPB link state database along with a synchronization mechanism carried in SPT BPDUs or SPB Hello PDUs. Locally on each Bridge, the Agreement Protocol logic is used to control the ISIS-SPB FDB updates and implement loop prevention logic. ISIS-SPB uses normal IS-IS procedures to update the link state database.

IS-IS uses SPB Hello PDUs and Link State PDUs (LSPs) to communicate between SPT Bridges. This clause (Clause 28) describes the relevant TLVs in the ISIS-SPB PDUs. Note that ISIS-SPB does not add any new PDU's to IS-IS it extends the currently defined PDUs.

Figure 28-2 through Figure 28-12 (in 28.12) illustrate the new TLVs and sub-TLVs for SPBV and SPBM. Note that SPBM, since it derives from PBB has the capability to indicate Service instance membership using the 24-bit I-SIDs. A default I-SID (I-SID 0x0000ff) maps to all SPT Bridges operating in SPBM mode allowing a default broadcast and group address capability for ISIS-SPB. The default I-SID is assigned to the default ECT Algorithm (LowPATHID, 28.7). I-SID group registrations via ISIS-SPB are similar to the MMRP capability but because they are delivered by IS-IS they involve no additional messaging. Group addresses are constructed by SPBM for each service instance/source and therefore do not require explicit advertisement.

The I-SID value of 0 is reserved by SPBM and is used as a deleted or free I-SID value in the TLVs. This reserved value may be used to avoid reorganizing LSPs when only one or a few I-SIDs are changed. This provides an optimization by allowing actual deletion (shuffling of the LSP contents) to be decoupled from the ISIS-SPB updates triggered by topology changes. LSPs may be reorganized during periodic updates thereby minimizing impacts.

SPBV and SPBM will operate either within an IS-IS level 1, or an ISIS level 2. As a result the TLVs specified here may propagate either in level 1 OR level 2 LSPs. IS-IS SPBM implementations shall support level 1 and may support level 2 operations. Multi-level ISIS-SPB is, however, for further study.

NOTE—IS-IS supports point-to-point links and shared LANs; however, only point-to-point is considered for ISIS-SPB in this specification. A future revision may add shared media. Clause 13 SPB description allow both point-to-point links and shared media.

28.1 ISIS-SPB control plane MAC

ISIS-SPB makes no changes to the IS-IS control plane addressing principles. However, ISIS-SPB defines two further addresses for the propagation of LSPs besides the three addresses already reserved by ISO (see Table 8-16). ISIS-SPB differentiates itself from IS-IS for Ipv4 etc. by the contents of the SPB Hello PDUs. The most important differentiation is the NLPID value for SPB (0xC1) [Annex W] which is carried in the SPB Hello protocols supported TLV and used to decide if a given adjacency should support SPB. ISIS-SPB carries this value in the Protocols Supported TLV (129) of IS-IS.

SPB operates either stand alone within an IS-IS instance, or shares an IS-IS instance and its adjacencies with other protocols as distinguished by the appropriate Network Layer Protocol Identifiers (NLPIDs). In order to

accomplish this, ISIS-SPB may as one option use the same control plane MAC addressing as the other NLPIDs.

SPB does not advertise its NLPID on shared media interfaces.

28.2 Formation and maintenance of ISIS-SPB adjacencies

ISIS-SPB uses the IS-IS three-way handshake for IS-IS point-to-point adjacencies described in IETF RFC 5303 to form adjacencies when they can be formed. This subclause specifies the conditions under which they may be formed, and the conditions under which the link may be used for forwarding after an adjacency has formed.

a) The initial exchange of SPB Hello PDUs between a pair of IS-IS instances advertises the NLPID value(s) supported by each Bridge. If any NLPID values match, it is anticipated that an adjacency will be established to support the matched Network Layer Protocol(s).

This standard specifies subsequent behavior only for adjacencies that support SPB (NLPID value 0xC1). ISIS-SPB supports MTs, and if more than one topology is instantiated, the procedures below are applied independently to each topology instance.

b) The link supporting the adjacency is initialized to “SPB Operationally down.” This is signaled by setting the SPB Link Metric in the Link Metric Sub TLV (28.12.7) to the value $(2^{24} – 1)$. All SPB Link Metric values $< (2^{24} – 1)$ signify “SPB Operationally up,” and the value advertised is that to be used in path computation.

c) The SPB Hello PDUs exchange MCID and Auxiliary MCID (28.4) values to determine whether VLANs are consistently allocated to an operational mode. If a Bridge detects that neither its MCID nor its Auxiliary MCID match the adjacency’s MCID or Auxiliary MCID, then the adjacency cannot be put into service, and no further tests are performed until an acceptable match has been achieved.

d) After an acceptable MCID match is achieved, configuration consistency for each Base VID in the topology is verified. The SPB Base VLAN-Identifiers sub-TLV (28.12.4) carried in SPB Hello PDUs carries, for each Base VID supported,

   1) The Base VID value.
   2) The ECT-ALGORITHM identifier (OUI or CID/Index) for that Base VID.
   3) The SPB Hello Use-Flag (1-bit), set if this Bridge or any Bridge in the SPT Region is using this Base VID for traffic.
   4) The M-Bit (1 bit), which indicates SPBM mode or SPBV mode.

   Consistency is determined as follows:

   — If either the local end or the far end SPB Hello Use-Flag of the adjacency are set, then only if the respective Base VID, ECT-ALGORITHM, and Mode bits match exactly is “matched” set for that Base VID.
   — If both local end and far end SPB Hello Use-Flags are clear, then “matched” is set (to allow maintenance of the adjacency during ECT Algorithm and mode reassignment).

Only if “matched” is true for all Base VIDs in the topology is the link supporting the adjacency set to “SPB Operationally up,” and usable for forwarding.

e) Once the link supporting the adjacency has advanced to “SPB Operationally up” as above, a Bridge shall only modify the ECT-ALGORITHM or Mode bit associated with any Base VID when both the local end and far end SPB Hello Use-Flags are clear. A Bridge shall not modify the ECT-ALGORITHM or Mode bit associated with any Base VID when either local or far end SPB Hello Use-Flag is set. To do so is indicative of a serious error condition.

f) If a Bridge detects that an adjacent Bridge has altered its advertisement of the ECT-ALGORITHM or Mode bit associated with any Base VID while either the local or far end SPB Hello Use-Flags is set, it shall declare the link supporting the adjacency "SPB Operationally down."

NOTE—If the error condition arises because of aberrant behavior by a single Bridge, the condition described will be detected by all its adjacencies, and the behavior specified will cause the aberrant Bridge to be isolated from the SPT Region. This is the least damaging mitigation of such a condition.

28.3 Loop prevention

The Group Address FDB entries for SPBV and SPBM are under the control of the ISIS-SPB database exchange. Group address entries can be ensured to be loop-free when two neighboring Bridges agree never to install potentially loop-forming state derived from an unsynchronized topology in the FDB (13.17, 6.5.4.1). This occurs by allowing ISIS-SPB to exchange link state messages and remove any older FDB entries that are no longer valid to any destination. Native IS-IS does not have a method for synchronizing the removal of state from the forwarding but it does have a method for synchronizing databases. ISIS-SPB augments this by using a digest of the database and adding the FDB condition. ISIS-SPB needs two modifications from regular IS-IS.

a) ISIS-SPB needs to remove any potential loop causing forwarding entries if its link state database is not synchronized with its neighbor Bridges.
b) ISIS-SPB needs to synchronize with its neighbors Bridges before installing Group Address FDB entries to prevent any potential loops.

The Agreement Protocol (13.17) specifies how this applies to ISIS-SPB.

28.4 The Agreement Digest

The Agreement Digest specified in this clause includes a Computed Topology Digest used to determine whether a neighboring Bridge is operating with identical network topology information and thereby determine whether frames may be safely forwarded to the neighbor.

The Agreement Digest field (Figure 28-1) comprises six elements:

— The Agreement Digest Format Identifier
— The Agreement Digest Format Capabilities
— The Agreement Digest Convention Identifier
— The Agreement Digest Convention Capabilities
— The Agreement Digest Edge Count
— The Computed Topology Digest

The Agreement Digest is carried as a structured 32-byte field in the ISIS-SPB Digest sub-TLV. Byte 1 is the most significant, Byte 32 is the least significant byte.These and all parameters carried in ISIS-SPB TLVs and sub-TLVs are encoded using the "big-endian" convention, in which lower numbered bits within each byte (those to the left) have higher significance.

28.4.1 Agreement Digest Format Identifier

The Agreement Digest Format Identifier (4 bits) is carried in the most significant 4 bits of Byte 1 of the Agreement Digest field. Its purpose is to allow alternative digests to be defined at some time in the future. This release of the standard defines Digest Format 0. All future upgrades to the standard protocol will require recipients to be able to receive and process digests of this format.

	Octet	Length
Agreement Digest Format Identifier	1	4 bits
Agreement Digest Format Capabilities	1	4 bits
Agreement Digest Convention Identifier	2	4 bits
Agreement Digest Convention Capabilities	2	4 bits
Agreement Digest Edge Count	3–4	2
Reserved (set to 0)	5–12	8
Computed Topology Digest	13–32	20

Figure 28-1—Agreement Digest field format

The Agreement Protocol (13.17) will not declare a topology match if the recipient does not support the Format value of this field, but otherwise it will operate as normal, so that the transmitter will receive an indication of the Digest Format Identifier and Capabilities of the receiver as a result of normal protocol operation.

28.4.2 Agreement Digest Format Capabilities

The Agreement Digest Format Capabilities (4 bits) is carried in the least significant 4 bits of Byte 1 of the Agreement Digest field. Its purpose is to allow alternative digest Formats to be defined and advertised at some time in the future. In this version of the standard it is transmitted as value 0 and ignored on receipt.

28.4.3 Agreement Digest Convention Identifier

The Agreement Digest Convention Identifier (4 bits) is carried in the most significant 4 bits of Byte 2 of the Agreement Digest field. Its purpose is to advertise the set of loop-free forwarding rules, for which the link state database information identified by the Digest acts as input, which are currently in use by the transmitter (13.17). The following rules are defined in this version of the standard:

— 1. indicates no digest match. Digests are exchanged but match is not required. Configured as off (Clause 17).

— 2. means the transmitter will continue loop-free forwarding of both multicast and unicast traffic either only after any change which occurs has been reflected in matched digests (strict agreement); or up to the limits of change specified by the rules in this version of the standard. This is the default. Configured as loopFreeBoth (Clause 17).

— 3. means the transmitter will continue loop-free forwarding of multicast traffic up to the limits of change specified by the rules in this version of the standard, and will continue forwarding of unicast traffic unconditionally. Configured as loopFreeMCastOnly (Clause 17).

NOTE—While it is recommended that all Bridges use the same convention, Bridges operate independently and the conventions can be different on individual Bridges. For loopFreeBoth and loopFreeMCastOnly as indicated, a Bridge may block all the respective traffic on change or allow “safe” traffic during change. Individual Bridges can have different definitions of “safety” applied to the forwarding allowed during digest mismatch.

28.4.4 Agreement Digest Convention Capabilities

The Agreement Digest Convention Capabilities (4 bits) is carried in the least significant 4 bits of Byte 2 of the Agreement Digest field. Its purpose is to advertise the set of loop-free forwarding rule conventions that are understood by the transmitter. The value 0 declares that the transmitter understands conventions 1 to 3 (above). Bridges conforming to this version of the standard transmit the value 0 and ignore this field on receipt.

28.4.5 Agreement Digest Edge Count

The Agreement Digest Edge Count (16 bits) is an unsigned integer carried in Byte 3 and Byte 4 of the Agreement Digest field. Its purpose is to provide one component of the Agreement Digest, which is simple to compute and powerful in detecting many simple topology mismatches.

This value is the sum modulo 2^{16} of all Edges in the SPB topology. Each point-to-point physical link is counted as two Edges, corresponding to its advertisement by ISIS-SPB in an LSP flooded from either end of the link.

If more that one ISIS-SPB topology is configured, the Agreement Digest Edge Count accumulates all Edges in all configured topologies. If Edges are absent in a particular topology, they have the value 0 for this summation.

NOTE—MT SPB allows different Link Metrics to be used in different topologies. The Agreement Digest format specified here can only achieve a match between topologies when exactly the same set of Bridges are present in all topologies but the requirement that MCIDs match for all Bridges in an SPT Region means that this is not an additional constraint.

28.4.6 The Computed Topology Digest

The overall procedure for constructing the Computed Topology Digest is to:

— Form a signature of each Edge in the topology by computing the MD5 hash (IETF RFC 1321 [B20]) of the significant parameters of the Edge, as defined below.

— Compute the Digest as the arithmetic sum of all Edges in the topology.

If more than one topology is declared in ISIS-SPB, the Computed Topology Digest covers all topologies declared, and this single value is advertised in the ISIS-SPB Digest sub-TLV. The SPB Digest sub-TLV is carried within the MT-Port-Cap TLV [IETF RFC 6165] with the MTID value of 0, which in turn is carried in an SPB Hello PDU.

NOTE 1—MD5 is widely reported to be cryptographically weak. This is not relevant in this application. What is required is a function exhibiting good avalanche properties such that signatures with potentially very similar input parameters have an infinitesimal probability of collision.

NOTE 2—This strategy allows the Digest to be incrementally computed when the topology changes, by subtracting the signatures of vanished Edges from the Digest and adding the signatures of new Edges. In general, the signature of an Edge therefore needs only to be computed once, when it is first advertised.

The input message to the MD5 hash for each Edge is constructed by concatenating the following fields in order, with the first field being the beginning of the message.

a) The Bridge Identifier (13.26.2) of the Bridge advertising the Edge with the greater Bridge Identifier value (8 bytes).
b) The Bridge Identifier of the Bridge advertising the Edge with the lesser Bridge Identifier value (8 bytes).
c) A variable number of 8-byte 3-tuples, one 3-tuple for each MTID (Clause 3) declared in ISIS-SPB. The 3-tuples are declared in descending order of MTID value, with the largest MTID declared first.

Each 3-tuple is constructed by concatenating the following fields in the order below:

d) A 2-byte field containing the 12-bit MTID value [IETF RFC 5120] in the least significant bits, with the most significant 4 bits of the field set to zero.
e) The SPB Link Metric [item c) in 12.25.6.1.2] for the Edge in this topology that has been advertised by the Bridge with the greater Bridge Identifier value (3 bytes).
f) The SPB Link Metric for the Edge in this topology that has been advertised by the Bridge with the lesser Bridge Identifier value (3 bytes).

If an Edge is not present in a topology, its SPB Link Metric is set to zero in that topology.

The value of the Computed Topology Digest is the arithmetic sum of all of the signatures returned by presenting every Edge message to MD5, treating the signature as an unsigned 16-byte integer and accumulating into a 20-byte integer. Every physical link is seen as two Edges, one advertised by each Bridge comprising the adjacency, and formally the Computed Topology Digest includes both.

NOTE 3—Although the Computed Topology Digest contains signatures for both Edges associated with each link, the construction defined above means that these are always identical. An implementation may choose to compute a single signature per link, and then double it before accumulating it into the Computed Topology Digest.

The value of the Computed Topology Digest is placed in Bytes 13 to 32 of the Agreement Digest field for transmission in the ISIS-SPB Digest sub-TLV.

Bytes 5 to 12 of the Agreement Digest field are unused in this version of this standard. They are set to zero on transmission and ignored on reception.

28.5 Symmetric shortest path tie breaking

When performing shortest paths computation there may be several equal cost shortest paths between the same Bridge pairs (27.17). In order to meet the congruency requirements, SPB requires that the computation produces a deterministic unique shortest path per SPT set independent of order or direction of computation.

The SPB symmetric (Clause 3) shortest path tie-breaking algorithm needs to be accurately specified or different versions of SPB would compute different SPTs. SPB requires symmetry and congruence in its unicast and multicast routing, so the operation of the algorithms defined for the base specification and constraints on their future extension are specified unambiguously.

NOTE—Exploration of path computation that produces various types of ECTs is beyond the scope of this standard.

Two mechanisms are used to provide for symmetric and congruent SPT calculation. The first mechanism addresses the possibility that different ends (nodes) of an adjacency advertise different values for the SPB Link Metric (28.12.7). To maintain determinism, the SPB shortest path calculation always uses the maximum of the two advertised SPB Link Metric values when accumulating path costs. The second mechanism addresses the situation in which two equal cost paths are found. To maintain determinism in this case, a tie-breaking algorithm is required that achieves the same result regardless of order of computation.

SPB is designed to support many tie-breaking algorithms for ECTs, and SPBM can assign traffic by I-SID to different B-VIDs assigned to different ECTs. SPB defines one required tie-breaking algorithm and an open framework for the creation of a very large number of additional algorithms. As part of the base standard, a number pre-defined tie-breaking algorithms are described using this framework with extensions for expansion in the future.

SPB accomplishes basic equal cost tie breaking by logically assigning a computation-order-independent identifier to each possible equal cost shortest path that it computes. This tie breaking is symmetric because it is independent of which direction the selection is done and it preserves reverse path congruency. This is referred to as the Path Identifier (PATHID). A PATHID is defined as the sorted list (ascending lexicographic order) of Bridge IDs that the path traverses including the endpoints.

When there are different equal cost shortest paths output by the SPF computation, each of them will have a unique PATHID. The PATHID for each distinct path will be the same whichever Bridge computes that PATHID. The PATHID will be the same for both the forward and reverse of a path (because they are sorted lists of Bridge-IDs). PATHIDs may be ranked and compared by successively comparing the sorted list of Bridge-IDs they contain. PATHID A is ranked “less than” PATHID B if it contains fewer Bridge-IDs:

e.g.: {9,15,22} < {7,8,9,10,22}

PATHID A is ranked “less than” PATHID B (of equal length) if its i’th Bridge-ID is less than B’s i’th Bridge-ID and all other Bridge-IDs up to the i’th are equal (lexicographic order).

e.g.: {9,15,22,99} < {9,15,22,100}

Both SPBV’s and SPBM’s default tie-breaking algorithm picks the equal cost path with the lowest PATHID as defined in the above ranking.

The above algorithm can be easily implemented efficiently by simply back tracking the two or more competing equal cost paths and picking the path that has the minimum PATHID between the fork and join points of the competing paths. A path selected in this manner will also be part of any longer shortest paths that transit the fork and join points, and so intermediate resolution of shortest path permutations can be performed and the state for discarded permutations need not be carried forward.

The Bridge Priority by default is the middle value equal to 8 of the 4-bit priority in the most significant part of the 2-byte field [8 × 4096 = 32 768 middle of the priority range] on all Bridges, and so does not affect the tie-breaking results. Bridge Priority can be tuned by the operator and will therefore affect the pre-defined tie-breaking algorithm(s) in a deterministic manner.

28.6 Symmetric ECT framework

Each tie-breaking method is uniquely identified by an ECT Algorithm. The ECT Algorithm is a 32-bit number that contains an OUI or CID and an index. This document specifies an initial set of SPB ECT Algorithms together with a framework for a large number of other algorithms. The OUI or CID allows organizations to specify and manage their own algorithms and behaviors and to document them independently either through the IEEE, or through other SDOs, or to keep them proprietary/experimental should they desire. The different SPB ECT Algorithms defined in this document use the IEEE 802.1 OUI (00-80-C2). Index values 1 through 16 are associated with symmetric ECT Algorithms while one additional non-ECT spanning tree algorithm is defined with Index value 0.

The ECT Algorithm is unique for an SPT Set. One or more Base VIDs may be associated with an ECT Algorithm; and this association is advertised both in LSPs to all other Bridges in the SPT region and also is exchanged in the SPB Hellos. A Base VID should not be used within the SPT region until all Bridges agree on the relationship. Temporary disagreement between the Base VIDs assigned is expected and permitted between Bridges as Base VIDs with new ECT Algorithms are configured. Disagreements are allowed when the Base VIDs is not in use. Base VIDs may share the same ECT Algorithm regardless of mode.

In SPBM, an I-SID is associated with a Base VID and thus by inference with an ECT Algorithm as well. This permits an operator to assign traffic to a certain ECT-ALGORITHM and to move it as required to achieve a degree of traffic balancing. In SPBM mode this Base VID is the B-VID directly.

In SPBV mode the Base VID shall be used to lookup and find the proper SPVID for the source under consideration during the setting of VLAN Registration Entries. A VLAN supported by SPBV can be forced to use the spanning tree of the IST in cases where the Bridges do not agree on the configuration or are short on SPVID resources.

Bridges must consider all SPT sets and populate forwarding even if they do not define a VID. An ECT Algorithm can be defined to operate using only data already advertised by ISIS-SPB (for example the Low and High PathID algorithms), or, it may require additional tuning parameters that cannot be foreseen. To accommodate a future ECT Algorithm need for tuning parameters SPB supports the concept of Opaque ECT data.

To allow for nodal- and link-based ECT behavior in future requirement the Opaque ECT data may be advertised under both SPB nodal and/or link data. The Opaque ECT data begins with the 32-bit ECT-ALGORITHM identifier but the remainder of the data format is specific to future ECT Algorithms and is therefore opaque to this document.

An example use of this framework could be as follows. Consider the tie breaking that can be done by using a minimum sum over a secondary link metric and a hash-based but deterministic assignment of such secondary metrics to every link in the network. Further consider these secondary link metrics as tunable. Initially a new value for this ECT Algorithm is assigned and registering it with the appropriate numbering authority for the OUI or CID. The hash functions that create the secondary link metrics based for example on the two Bridge-IDs at each end of the link, could be defined. Then a format for a 32-bit opaque secondary metric could be defined which would be advertised as opaque data under the link data and prefixed with the ECT-ALGORITHM index for the new tie breaker. Migration to this new tie breaker would proceed in a manner consistent with any ECT Algorithm (28.9).

28.7 Symmetric ECT

In the case of multiple equal cost paths, multiple ECTs may be computed, in fact most efficient shortest path computations like Dijkstra actually produce all shortest paths from a root, i.e., an SPF tree, and different unique trees emerge depending on the tie breaking employed at the branch points. These different trees are distinguished in the forwarding plane by using SPVIDs (SPBV) or B-VIDs and B-MAC SAs (SPBM) for each “active topology”. In order to be repeatable a unique tie breaker (ECT Algorithm) is chosen for each SPT set as described in 28.5. Typically a small number of B-VIDs would satisfy most requirements for equal cost routes in the case of SPBM.

SPBV and SPBM support a set of symmetric (Clause 3) equal cost paths between any pair of Bridges for a given SPB instance/MTID. The symmetric shortest path algorithms are identified by the ECT Algorithm using the IEEE 802.1 OUI=00-80-C2 and with Index values 0..16. Index value 0 is somewhat special in that it relates the VID used for the CIST and is not a shortest path algorithm but is instead the spanning tree algorithm. The remaining algorithms are shortest path algorithms: The LowPATHID algorithm (index = 1) is the default SPT path computation tie breaker. SPB uses LowPATHID as the default SPT tie-breaking algorithm. SPB can use any alternate tie-breaking algorithm for another ECT when it is configured. The other defined algorithms use a computed shuffle of the LowPATHID algorithm. For example the HighPATHID ECT-ALGORITHM=<OUI=00-80-C2:index = 2> is just a rank inversion, which ones-complements the Bridge-IDs prior to doing the same comparisons as the LowPATHID algorithm. The remaining 14 pre-defined algorithms have indexes 3..16 and are defined in terms of a bit mask that they XOR the Bridge-IDs with prior to finding the minimum PATHID. Since they XOR over all 8 bytes, which include the Bridge-Priority and the SPB System Identifier, these algorithms can be tuned in deterministic ways by adjusting the Bridge-Priority. SPBM can advertise a Base VID for each of these unique symmetric shortest paths through the ECT SPB Instance sub-TLV (28.12.5).

SPB assigns a unique ECT Algorithm to a Base VID in the Base VID sub-TLV (28.12.4) and the SPB Instance sub-TLV (28.12.5). To allow migration between different ECT Algorithms, further ECT Algorithm and Base VID bindings may be advertised, unused, without interfering with the operation of currently used ECT Algorithms and Base VIDs. Once Bridges are configured to support the new ECT Algorithm and share a consistent Base VID for this algorithm, the algorithm may then be used by mapping I-SIDs to the Base VID for the desired ECT Algorithm.

SPBV also assigns a unique Base VID to each ECT Algorithm; however, the actual data path VID used depends on the source. Therefore, an SPVID shall be specified in the SPVID field in conjunction with the Base VID and ECT Algorithm in the SPB Instance sub-TLV. A similar procedure can be used with SPBV to introduce a Base VID that would not carry traffic until fully configured. Then services could be switched to the new VLAN. This is no different than introducing a new VLAN on RSTP for example.

28.8 Symmetric ECT Algorithm details

The exact method applied for computing the active topology of a VLAN assigned to ISIS-SPB control is determined by the ECT Algorithm configured for the given VLAN. A set of symmetric ECT Algorithms is defined to calculate SPT Sets for SPBV or SPBM VLANs. Two ECMP ECT Algorithms (44.1.2) are defined to calculate SPTs and shared trees for ECMP (Clause 44). Five explicit ECT Algorithms (45.1) are defined for VLANs associated with Explicit Trees (Clause 45).

Each of the standard symmetric ECT-ALGORITHM values is formed using the OUI=00-80-C2 and the Index=1..16. An Algorithm Mask is specified for each Index, and is exclusive-ORed with each octet of each of the Bridge Identifiers (2 octet Bridge Priority concatenated with the 6 octet SPB System Identifier) to generate Masked Bridge Identifiers for each of the candidate paths. Given any two paths, the one chosen for a given ECT Algorithm has the lowest PATHID formed from the ranked masked Bridge Identifiers, which will necessarily include a lowest masked Bridge Priority, excluding those common to both paths. This comparison gives the greatest weight to the (masked) Bridge Priority of each Bridge Identifier, allowing the path selection to be managed/tuned without creating additional identifiers or identifier components for each Bridge. The ECT-ALGORITHM values and corresponding Masks and their effects, in terms of prioritizing path selection by Bridge Priority, are given in Table 28-1.

Table 28-1—Bridge Priority Masking

ECT-ALGORITHM	Algorithm MASK	Effect of using MASK on priority nibble
00-80-C2-01	0x00	The selected path includes Bridge with best (numerically lowest) Bridge Identifier after masking. In this case the masking 0x00 no effect and original administered Bridge priority values apply. When Bridge priority value is equal for two Bridge identifiers the lower system identifier determines the priority. (0,1,2,3,4,5,6,7,8,9,10,11,12,13,14,15).
00-80-C2-02	0xFF	The selected path includes Bridge with best priority (numerically lowest) Bridge Identifier after masking. In this case the masking 0xFF reverses the original administered Bridge priority values. When Bridge priority value is equal for two Bridge identifiers the lower system identifier determines the priority. (15,14,13,12,11,10,9,8,7,6,5,4,3,2,1,0). Read vector as administered priority 0 equals 15, administered priority 15 equals 0 and so on.
00-80-C2-03	0x88	Bridges with Bridge Priority 8 will be treated as best priority for path selection, followed by Bridge Priorities of 9, 10, 11, and so on. (8,9,10,11,12,13,14,15,0,1,2,3,4,5,6,7). Read vector as administered priority 0 equals 8, administered priority 8 equals 0.
00-80-C2-04	0x77	Bridges with Bridge Priority 7 will be treated as best priority for path selection, followed by Bridge Priorities of 6, 5, 4, and so on. (7,6,5,4,3,2,1,0,15,14,13,12,11,10,9,8). Read vector as administered priority 0 equals 7, administered priority 7 equals 0.
00-80-C2-05	0x44	(4,5,6,7,0,1,2,3,12,13,14,15,8,9,10,11)
00-80-C2-06	0x33	(3,2,1,0,7,6,5,4,11,10,9,8,15,14,13,12)
00-80-C2-07	0xCC	(12,13,14,15,8,9,10,11,4,5,6,7,0,1,2,3)
00-80-C2-08	0xBB	(11,10,9,8,15,14,13,12,3,2,1,0,7,6,5,4,)
00-80-C2-09	0x22	(2,3,0,1,6,7,4,5,10,11,8,9,14,15,12,13)
00-80-C2-0A	0x11	(1,0,3,2,5,4,7,6,9,8,11,10,13,12,15,14)
00-80-C2-0B	0x66	(6,7,4,5,2,3,0,1,14,15,12,13,10,11,8,9)

Table 28-1—Bridge Priority Masking *(continued)*

ECT-ALGORITHM	Algorithm MASK	Effect of using MASK on priority nibble
00-80-C2-0C	0x55	(5,4,7,6,1,0,3,2,13,12,15,14,9,8,11,10)
00-80-C2-0D	0xAA	(10,11,8,9,14,15,12,13,2,3,0,1,6,7,4,5)
00-80-C2-0E	0x99	(9,8,11,10,13,12,15,14,1,0,3,2,5,4,7,6)
00-80-C2-0F	0xDD	(13,12,15,14,9,8,11,10,5,4,7,6,1,0,3,2)
00-80-C2-10	0xEE	(14,15,12,13,10,11,8,9,6,7,4,5,2,3,0,1)

NOTE 1—In these algorithms, the Algorithm Mask is applied to all octets of each Bridge Identifier. Thus if two alternative paths include only Bridges with one or a few Bridge Priorities, the Algorithm Mask will still reorder their priorities for inclusion on the path as it acts on the rest of the SPB System Identifier component of the Bridge Identifier field.

NOTE 2—If the two priority bytes in the 8-byte Bridge Identifier are all equal, then all Bridges have equal priority and ECT-ALGORITHM values 00-80-C2-01 and 00-80-C2-02 are exactly Low and High PATHID as described in 28.5.

28.9 ECT Migration

For orderly migration, each Base VID to ECT Algorithm assignment also has associated flags indicating active usage of the Base VID by services. The Use-Flag in the SPB Base VLAN-Identifiers sub-TLV (28.12.4) indicates a Bridge's awareness of use of the Base VID somewhere in the SPT Region, and the U-bit in the SPB Instance sub-TLV (28.12.5) indicates local use of this Base VID. The Use-Flag in the SPB Base VLAN-Identifiers sub-TLV is carried in the SPB Hello PDU, and is set once the Bridge advertising the algorithm has started either using or seeing the use of that ECT-ALGORITHM. ISIS-SPB enforces the following rules with respect to ECT Algorithms and their usage in order to protect the SPB network from outages created by incorrect configuration. If neighbors disagree on a Base VID to ECT-ALGORITHM assignment, then use of the adjacency for SPB traffic is permitted (i.e., the SPB Link Metric may be set less than $2^{24} - 1$) only if both neighbors' Use-Flags associated with the Base VID are cleared (28.2).

If a new ECT Algorithm is implemented in all Bridges of an SPT Domain and intended to be used by a Base VID, then the assignment of the Base VID to the new ECT-ALGORITHM with Use-Flag cleared is first configured in the SPT Domain on a Bridge by Bridge basis. As soon as this configuration is complete, services (I-SIDs in SPBM or SPVIDs in SPBV) may be assigned to the given Base VID, which causes the local U-bit to be set, which will in turn cause the Use-Flag to be set for the given Base VID.

SPBV and SPBM have different migration capabilities after the introduction of a new ECT Algorithm. The following subclauses describe how SPBV and SPBM use a newly introduced ECT Algorithm.

28.9.1 Use of a new ECT Algorithm in SPBV

A new ECT Algorithm, which is implemented by each Bridge of an SPT Domain, gets to be used if it is configured to support a VLAN. In SPBV mode, the application of a new ECT Algorithm typically coincides with the introduction of a new VLAN supported by SPBV. That is, the Base VID of the new VLAN is assigned to the new ECT-ALGORITHM in the SPB Hello PDU Base VID and SPB Instance sub-TLVs (28.9). ISIS-SPB then allocates (27.10) the SPVIDs necessary for the support of the new VLAN. To support in-service upgrade from one set of VID / ECT Algorithm allocations to another, SPT Bridges allow graceful configuration of those services. Provided there is an operating SPBV or SPBM VLAN in a region, SPT Bridges can be configured within the Region for a new VLAN on a Bridge by Bridge basis. As long as the SPT Region is connected the Bridges supporting the new VLAN do not need to be directly connected.

Intermediate Bridges are capable of populating forwarding without terminating services allowing them to participate in the VLAN.

The migration of a VLAN from an old ECT Algorithm to a new ECT Algorithm can be performed by the reassignment of the Base VID of the VLAN. That is, the Base VID is assigned to the new ECT-ALGORITHM instead of the old ECT-ALGORITHM on a Bridge by Bridge basis. In SPBV the forcing of one of the Bridges Base-VIDs to use the spanning tree algorithm as opposed to another algorithm forces all of the Bridges in the SPT region using that Base VID to spanning tree. Migration can then proceed to the new Base VID assignment until the last Bridge is configured to use the new ECT-ALGORITHM. The new assignment is then propagated in SPB Hello PDU Base VID and SPB Instance sub-TLVs (28.9) by ISIS-SPB within the SPT Domain. As soon as each SPT Bridge is configured with the Base VID assignment to the new ECT-ALGORITHM, the spanning tree assignment on the last Bridge is cleared.

NOTE 1—ISIS-SPB automatically performs the allocation and release of SPVIDs during the migration. The SPVIDs allocated for the Base VID old ECT-ALGORITHM assignment are released as soon as the assignment has been broken. These SPVIDs might be then allocated for the Base VID new ECT-ALGORITHM assignment. That is, there is no need for additional SPVID allocations if a Base VID supported by SPBV is migrated from an old ECT-ALGORITHM to a new one.

NOTE 2—SPBV does not support hitless migration. That is, the migration of a VLAN from an old ECT-ALGORITHM to a new ECT-ALGORITHM may cause traffic outage.

28.9.2 Use of a new ECT Algorithm in SPBM

SPBM offers the ability to map I-SIDs to Base VIDs as a load balancing option. In topologies with multiple equal cost paths the ability to spread traffic on a per I-SID basis comes from using the Base VIDs with different algorithms as specified in this clause.

When an I-SID is configured to be associated with a Base VID, that Base VID shall be consistently associated with the same ECT-ALGORITHM throughout the SPT Domain. Once at least one I-SID has been assigned to a Base VID the U-bit is set and advertised in subsequent LSPs, which also causes the Use-Flag to be set in SPB Hello PDUs.

SPBM supports in-service migration of an I-SID from an old ECT Algorithm to a new ECT Algorithm supported by each Bridge of an SPT Domain. In order to accomplish this, two complete Base VIDs must be configured in the SPT Domain. Then an I-SID under migration can be assigned to two Base VIDs at the same time: the old Base VID (old ECT-ALGORITHM), and the new Base VID (new ECT-ALGORITHM). The U-bit (in the SPB Instance sub-TLV, 28.12.5) is set by the advertising Bridge when there is at least one service using this VID. This propagates throughout the SPT domain, and any Bridge seeing at least one U-bit set in received LSPs (signifying that the indicated Base VID is being used by a service somewhere) sets the Use-Flag in its SPB Base VLAN-Identifiers sub-TLV (28.12.4).

I-SIDs will have originally been configured to be associated with the old Base VID (28.12.10). No filtering entry is set for the new Base VID in the FDBs as there is no Transmitter set on the new Base VID yet. I-SIDs can be configured to be associated with the new Base VID. Care must be taken to ensure the new Base VID is configured in all the required places. When a particular I-SID has been added to a new Base VID, ISIS-SPB detects that the I-SID is now associated with two Base VIDs and at each location that I-SID may receive traffic on either Base-VID. During this period individual addresses are available under both Base VIDs. The setting of the R and T bits still determines whether the group addresses are populated for each Bridge supporting that I-SID in either Base VID. In other words the same rules for a single Base VID are followed but two base VIDs are temporarily in use for received traffic. Traffic is “rolled” from the old Base VID to the new one by administrative reassignment of the I-SID at each service end-point from the old to the new B-VID. This can be an atomic action, and so at any instant only one Base VID will be used by any service originating frames. The association of the I-SID to the old Base VID is removed once all I-SIDs are configured to one Base VID. Furthermore, if this is the last I-SID removed from a Base VID the U-bit is cleared (in the SPB Instance sub-TLV) for the old Base VID to ECT-ALGORITHM assignment. Eventually the Use-Flag carried in the SPB Hello PDU will be cleared when all the Bridges have been configured.

28.10 MAC address registration

ISIS-SPB creates MAC Address Registration Entries (8.8.4) for group addresses in order to reach the members of a group. The group addresses are locally administered in case of SPBM (27.16), thus, they are only significant inside the SPT Region.

ISIS-SPB also installs MAC Address Registration Entries for universally administered group addresses as they might be used by SPBV. Furthermore, ISIS-SPB provides interworking with MMRP at the Boundary Ports of an SPT Region. That is, ISIS-SPB interprets MMRPDUs received at a Boundary Port and assembles the proper ISIS-SPB TLVs in order to advertise the corresponding MAC address registration inside the SPT Region. Furthermore, ISIS-SPB assembles and issues MMRPDUs on Boundary Ports if MAC address registration needs to be propagated outside of the SPT Region.

When an MMRPDU is received on a Boundary Port, ISIS-SPB disseminates the registration by sending LSPs with an SPBV MAC Address sub-TLV (28.12.9) filled according to the registration received from the MMRPDU. The MAC Address and Base VID values shall be copied from the MMRPDU, with the R bit set and T bit cleared. The SR bits (28.12.9) are set according to the Group service requirement information carried in the MMRPDU. When processing received SPBV MAC Address sub-TLVs that have the R bit set, SPT Bridges at the boundary of an SPT Region shall check whether they should filter or forward the frames received on their Boundary Port in the VLAN for which the registration applies. If the option is to forward frames, then they also send the SPBV MAC Address sub-TLV into the SPT Region for the MAC address under registration; but set the T bit, clear the R bit and for the VID value use the SPVID allocated to the given VLAN. ISIS-SPB then creates MAC Address Registration Entries inside the SPT Region based on the SPBV MAC Address sub-TLVs. Furthermore, if the Boundary Port is in the given VLAN's member set, then ISIS-SPB assembles the proper MMRPDU and issues it on the Boundary Port.

Besides interworking with MMRP at Boundary Ports, ISIS-SPB also takes into account the Registrar Administrative Control parameters (10.7.2).

NOTE—Creation of unnecessary MAC Address Registration Entries can be prevented by using the "Registration Forbidden" parameter for the proper Ports and VLANs.

28.11 Circuit IDs and Port Identifiers

IS-IS allows the formation of multiple adjacencies between two routers. ISIS-SPB supports only a single logical adjacency per MTID. Link Aggregation allows a single ISIS-SPB adjacency to cover multiple links, and this is the only method defined in this version of this standard by which multiple links between neighbors are supported. In cases where multiple potential adjacencies exist, each pair of peers using ISIS-SPB should choose the link with the lowest Local Circuit ID on the Bridge with the better (numerically lower) SPB System Identifier as the link over which to send and receive frames.

Procedures for using multiple adjacencies are not specified by this standard.

28.12 ISIS-SPB TLVs

All SPB TLVs and sub-TLVs are described. SPBV and SPBM share most of the same TLVs. Multi-Topology (MT) [Annex W] is introduced as well, but multiple SPT instances, each supporting a different VLAN, and each using either SPBV or SPBM can be described in a single topology instance. MT instances allow different topologies to be advertised, for example if there is a desire to use different metrics since there is only a single metric scheme within a topology.

SPB adds one new TLV and several new sub-TLVs that can be added to IS-IS PDUs, as described below. The new ISIS-SPB data have been organized to support multiple topologies within a single IS-IS instance. Each of the new sub-TLVs can be included in a TLV containing a topology instance identifier (MTID) value (as per [MT]) so that the computations can operate only on sub-TLVs specific to their topology instance. The intent of MT is to support the use of multiple metric sets when required. The construction of the MCID and the Agreement Digest (13.17, 28.4) requires that all SPT Bridges in an SPT region appear in all MT instances.

All parameters carried in the ISIS-SPB (sub-)TLVs defined below are encoded using the "big-endian" convention, in which higher significance bytes and bits within each byte appear to the left of and above bytes and bits of lower significance.

28.12.1 MT-Capability TLV

The MT-Capability TLV (Figure 28-2) is a top-level TLV for LSPs that provides Multi-Topology context. It identifies the MTID for sub-TLVs in LSPs.

	Octet	Length
Type (144)	1	1
Length (2)	2	1
Overload Bit	3	1 bit
reserved	3	3 bits
MTID	3–4	12 bits

Figure 28-2—MT-Capability TLV

a) Type (8 bits) Value 144
b) Length (8 bits)

   Total number of bytes contained in the value field.
c) Overload Bit (1 bit)

   The overload bit is an ISIS-SPB MT instance-specific overload bit.
d) MTID (12 bits)

   This is used to provide the ISIS-SPB Multi-Topology context for SPB sub-TLVs. This should be 0 when there is only one topology instance.

28.12.2 SPB MCID sub-TLV

This sub-TLV (Figure 28-3) shall be included in an MT-Port-Cap TLV [IETF RFC 6165] with MTID equal to 0 in SPB Hello PDUs to announce the Bridge's MCID (13.8). This information should be the same on all Bridges in the topology being controlled by this ISIS-SPB instance. The MCID is controlled solely by configuration and is a digest of the protocol assignments for all possible VIDs. Two MCIDs are carried to allow transitions between configurations when the changes are non-critical. If neither MCID advertised by a neighbor matches either MCID on this Bridge the adjacency is a Region boundary.

	Octet	Length
Type (4)	1	1
Length (102)	2	1
MCID	3–53	51
Aux MCID	54–104	51

Figure 28-3—SPB MCID sub-TLV

a) Type (8 bits) Value 4

b) Length (8 bits)

Total number of bytes contained in the value field.

c) MCID (51 bytes)

The complete MCID defined in (13.8) that identifies an SPT Region.

d) AUX-MCID (51 bytes)

In the case of migration and where the MCID will change but in a non-critical way, this MCID contains the previous advertised MCID. The neighbor will not drop an adjacency if at least one of these MCIDs matches either of its MCIDs.

28.12.3 SPB Digest sub-TLV

This sub-TLV (Figure 28-4) shall be included in an MT-Port-Cap TLV with MTID 0 in SPB Hello PDUs. The ISIS-SPB Agreement Digest (13.26.1, 28.4) is computed based on current topology and it changes when significant topology changes. The Agreement Digest is a key input into the Agreement Protocol (13.17), which provides multicast loop prevention. During the propagation of LSPs the Agreement Digest will vary between neighbors until the LSPs are common. The digest is a summarized means of determining agreement between nodes on the distance to all multicast roots, hence is essential for loop prevention. For each SPT where it has been determined the distance to the root has changed, unsafe multicast forwarding is blocked until the exchanged digests match.

	Octet	Length
Type (5)	1	1
Length (33)	2	1
reserved	3	3 bits
V	3	1 bit
A	3	2 bits
D	3	2 bits
Agreement Digest	4–35	32

Figure 28-4—SPB Digest sub-TLV

a) Type (8 bits) Value 5

b) Length (8 bits)

Total number of bytes contained in the value field.

c) V (1 bit)

The Agreed Digest Valid Bit (13.27.7, 13.27.9). This bit is populated and read from the Agreement Logic.

d) A (2 bits)

The agreement number 0–3, which aligns with BPDUs agreement number concept (13.27.11). When the Agreement Digest for this node changes this number is updated and sent in the SPB Hello.

e) D (2 bits)

The discarded agreement number 0–3, which aligns with BPDUs agreement number concept (13.27.12). When the Agreement Digest for this node changes this number is updated. Once an Agreement has been sent it is considered outstanding until a matching or more recent Discarded Agreement Number is received.

f) Agreement Digest (32 bytes)

An Agreement Digest as described in 28.4.

28.12.4 SPB Base VLAN-Identifiers sub-TLV

This sub-TLV (Figure 28-5) is included in an MT-Port-Cap TLV in an SPB Hello PDU to indicate the ECT Algorithms for the Base VIDs (and by implication the VID(s) used on the forwarding path for each SPT Set for a VLAN identified by a Base VID) that are in use. This information should be the same on all Bridges in the topology identified by the MT-Port-Cap TLV in which it is carried. Discrepancies between neighbors with respect to this sub-TLV are temporarily allowed during reconfiguration but at all times the active Base-VIDs (as determined by the state of the Use-Flag carried in this sub-TLV) shall agree and use the same ECT-ALGORITHM.

In the case of SPBM, the Base VID is the B-VID used to forward frames. In the case of SPBV, each source uses a different SPVID and a Base VID is used for frames transmitted on the IST. One or more Base VIDs are associated with an ECT Algorithm. This structure supports multiple SPT Sets within an IS-IS topology instance for both SPBV and SPBM. It also allows ECMP (Clause 44) for SPBM and the use of Explicit Trees (Clause 45) both for SPBV and SPBM within the same IS-IS topology instance supporting the SPT Sets.

		Octet	Length
	Type (6)	1	1
	Length (6n)	2	1
ECT-VID Tuple 1	ECT Algorithm	3–6	4
	Base VID	7–8	12 bits
	U	8	1 bit
	M	8	1 bit
	reserved	8	2 bits
...			
ECT-VID Tuple n	ECT Algorithm	(6n–3)–6n	4
	Base VID	(6n+1)–(6n+2)	12 bits
	U	6n+2	1 bit
	M	6n+2	1 bit
	reserved	6n+2	2 bits

Figure 28-5—SPB Base VLAN-Identifiers sub-TLV

a) Type (8 bits) Value 6

b) Length (8 bits)

The size of the value is ECT-VID Tuples*6 bytes. Each 6-byte part of the ECT-VID tuple is formatted as described below.

c) ECT-ALGORITHM (4 bytes)

The ECT-ALGORITHM is advertised when the Bridge supports a given ECT-ALGORITHM (by OUI or CID/Index) on a given Base VID.

d) Base VID (12 bits)

The Base VID that is associate with the SPT Set.

e) Use-Flag (1 bit)

The Use-Flag is set if this Bridge, or any Bridge in the SPT Region is currently using this ECT-ALGORITHM and Base VID. The Use-Flag is calculated as the logical OR of the

U-bit values of all Bridges in the region, as found in their SPB Instance sub-TLV (28.12.5) in the link state database. This definition includes the U-bit value of this Bridge.

f) M-Bit (1 bit)

The M-bit indicates if this is SPBM when set to 1 or SPBV mode when set to 0.

g) 2 Reserved Bits set to 0.

28.12.5 SPB Instance sub-TLV

This sub-TLV (Figure 28-6) is carried within an MT-Capability TLV in the fragment ZERO LSP. It identifies the Bridge uniquely and identifies the ECT-ALGORITHM values supported by the Bridge and the Base VIDs and SPVIDs assigned to those algorithms. For SPBM, only the Base VID is valid and the SPVID is set to zero. In the case of SPBV, the Base VID is associated with the SPVID used for forwarding by the Bridge originating the TLV. There can be multiple ECT-ALGORITHM values specifying a number of ECTs. Alternatively, the ECT-ALGORITHM value can indicate that the VLAN is assigned to ECMP operation (Table 44-1) or to explicit path control (Table 45-1).

		Octet	Length
	Type (1)	1	1
	Length	2	1
	CIST Root Identifier	3–10	8
	CIST External Root Path Cost	11–14	4
	Bridge Priority	15–16	2
	reserved	17–18	11 bits
	V	18	1 bit
	SPSourceID	18–20	20 bits
	Number of Trees	21	1
VID Tuple 1	U	22	1 bit
	M	22	1 bit
	A	22	1 bit
	reserved	22	5 bits
	ECT Algorithm	23–26	4
	Base VID	27–28	12 bits
	SPVID	28–29	12 bits
...			
VID Tuple n	U	8n+14	1 bit
	M	8n+14	1 bit
	A	8n+14	1 bit
	reserved	8n+14	5 bits
	ECT Algorithm	(8n+15)–(8n+18)	4
	Base VID	(8n+19)–(8n+20)	12 bits
	SPVID	(8n+20)–(8n+21)	12 bits

Figure 28-6—SPB Instance sub-TLV

a) Type (8 bits) Value 1

b) Length (8 bits)

Total number of bytes contained in the value field.

c) CIST Root Identifier (64 bits)

The CIST Root Identifier is for SPB interworking with RSTP and MSTP at SPT Region Boundaries. This is an imported value from a spanning tree.

d) CIST External Root Path Cost (32 bits)

The CIST External Root Path Cost is the cost from the spanning tree algorithm to the Root.

e) Bridge Priority (16 bits)

Bridge priority is the 16 bits that together with the low 6 bytes of the SPB System Identifier form the Bridge Identifier. The Bridge Identifier is the spanning tree compatible Bridge identifier. This is configured exactly as specified in IEEE Std 802.1D-2004 [B12]. This allows SPB to build a

compatible spanning tree using link state by combining the Bridge Priority and the SPB System Identifier to form the 8-byte Bridge Identifier. The 8-byte Bridge Identifier is also the input to the 16 pre-defined ECT tie-breaker algorithms.

f) V bit (1 bit)

The V bit (SPBM) indicates this SPSourceID is auto allocated (27.10). If the V bit is clear the SPSourceID has been configured and shall be unique. When a Bridge joining an SPT Region has formed at least one SPB adjacency, it can discover the previously allocated SPsourceIDs and it will allocate a SPSourceID according to the allocation logic (27.10).

g) SPSourceID (20 bits)

The SPSourceID (SPBM) is a 20-bit value used to construct group MAC address (27.15) for multicast frames originating from the origin (SPT Bridge) of the LSP that contains this sub-TLV. SPSourceID may be 0 if it has not been allocated (27.10) or if there is no SPBM service configured. When SPSourceID is 0 all information pertaining to this MTID SPB instance will be distributed but not acted upon until a valid SPSourceID is populated. If the SPSourceID conflicts with another SPSourceID from another Bridge the tie-breaker rules determine the winning Bridge (27.10).

h) Number of Trees (8 bits)

The Number of Trees is set to the number of VID tuples that follow (minimum one). The following seven fields make up a VID tuple. A sequence of VID tuples can occur in any order.

1) U-Bit (1 bit)

The U-bit is set if this Bridge is currently using this ECT-ALGORITHM for I-SIDs it sources or sinks or the SPVIDs it sources. This is importantly different from the Use-Flag found in the SPB Hello, which is set if a Bridge sees other nodal U-bits are set OR it sources or sinks itself.

2) M-Bit (1 bit)

The M-bit indicates if this is SPBM when set to 1 or SPBV mode when set to 0.

3) A bit (1 bit)

The A bit (SPB) when set declares this is an SPVID with auto allocation (27.10). If the SPVID value is zero, VID will be allocated once the Bridge has synchronized the IS-IS LSPs. Neighbor Bridges can distribute the LSPs but shall not populate FDBs (forwarding) for traffic from a Bridge that has an SPVID of 0. When the Bridge allocating is synchronized with the IS-IS adjacency, it will allocate one or more SPVIDs according to the allocation logic (27.10).

4) Reserved (5 bits)

Five bits reserved for future use shall be set to 0.

5) ECT-ALGORITHM (4 bytes)

ECT-ALGORITHM is advertised when the Bridge supports a given ECT-ALGORITHM (by OUI or CID/Index) on a given VID. This declaration shall match the declaration in the SPB Hello PDU originating from the same Bridge. When migrating from one algorithm to another discrepancies between algorithm and Base VID on different Bridges are allowed if the Use-Flag is clear.

6) Base VID (12 bits)

The Base VID that associated the SPT Set via the ECT-ALGORITHM.

7) SPVID (12 bits)

The SPVID is the Shortest Path VID when using SPBV mode. In SPBM mode it is not used and should be set to 0.

28.12.6 SPB Instance Opaque ECT Algorithm sub-TLV

There are multiple ECT Algorithms defined for SPB, and in the future additional algorithms may be defined. These algorithms may use this optional sub-TLV (Figure 28-7) to carry new algorithm parameters, for example, tie-breaking data. There are two broad classes of ECT Algorithm: one which uses nodal data to break ties and one which uses link data to break ties. This sub-TLV can associate opaque data with a node.

This sub-TLV is carried in an MT-Capability TLV in an LSP (along with a valid SPB Instance sub-TLV). Multiple copies of this sub-TLV may be carried for different ECT-ALGORITHM values related to the node.

	Octet	Length
Type (2)	1	1
Length	2	1
ECT-ALGORITHM	3–6	4
ECT Information	7–(Length+2)	variable

Figure 28-7—SPB Instance Opaque ECT-ALGORITHM sub-TLV

a) Type (8 bits) Value 2

b) Length (8 bits)
Total number of bytes contained in the value field.

c) ECT-ALGORITHM (4 bytes)
ECT-ALGORITHM is advertised when the Bridge supports a given ECT-ALGORITHM (by OUI or CID/Index) on a given VID.

d) ECT Information (variable)
ECT-ALGORITHM Information of variable length.

28.12.6.1 ECMP ECT Algorithm sub-TLV

This TLV (Figure 28-8) is not required for SPBM symmetric ECT operation and is optional for SPBM ECMP. This sub-TLV can be used to advertise a Bridge Priority value (most significant 2 bytes of the Bridge Identifier) to be used in shared tree root Bridge selection (44.1.2) when using the normal Bridge Priority (13.26.2) will not produce the desired result. Since Bridge Priority influences both source rooted tree structure and shared tree root selection, this optional sub-TLV is provided for situations in which the desired outcome for both of these selections cannot be achieved using a single Bridge Priority. This sub-TLV associates an alternate Bridge Priority [item c) in 12.25.14.1.2] with a node for use with a particular Tie-Break Mask. The alternate Bridge Priority is used instead of the normal Bridge Priority when the associated Tie-Break Mask is used to select a shared tree root Bridge. This enables greater control over root Bridge selection for shared trees, when needed. This sub-TLV is carried in an MT-Capability TLV in an LSP (along with a valid SPB Instance sub-TLV).

		Octet	Length
	Type (2)	1	1
	Length	2	1
	ECT-ALGORITHM (00-80-C2-11)	3–6	4
Tuple 1	Tie-Break Mask	7	4 bits
	reserved	7	4 bits
	Bridge Priority	8–9	2
...			
Tuple n	Tie-Break Mask	(3n+4)	4 bits
	reserved	(3n+4)	4 bits
	Bridge Priority	(3n+5)–(3n+6)	2

Figure 28-8—ECMP ECT-ALGORITHM sub-TLV

a) Type (8 bits) Value 2

b) Length (8 bits)
Total number of bytes contained in the value field.

c) ECT-ALGORITHM (4 bytes)
ECT-ALGORITHM is 00-80-C2-11 for ECMP.

d) Tie-Break Mask (4 bits)

A 4-bit mask that is repeated to form a 64-bit mask used in selecting the low Bridge Identifier from a set of Bridge Identifiers. This selection process is used to select a shared tree root Bridge.

e) Bridge Priority (16 bits)

Bridge priority is the 16 bits that together with the low 6 bytes of the SPB System Identifier form the Bridge Identifier. This Bridge Priority is used to form the Bridge Identifier used to select a shared tree root bridge using the mask identified by the accompanying Tie-Break Mask field.

28.12.7 SPB Link Metric sub-TLV

This sub-TLV (Figure 28-9) is included in an Extended IS Reachability TLV (type 22) [IETF RFC 5305] or MT Intermediate Systems TLV (type 222) [IETF RFC 5120]. If this sub-TLV is not present for an IS-IS adjacency then that adjacency must not carry SPB traffic for the given topology instance. The maximum metric value ($2^{24} - 1$) signifies that the link shall not be used for SPB traffic (it is to treated as "SPB operationally down").

NOTE—In ECMP the elimination of symmetry requirements could allow the use of a different metric for each link direction; however, to maintain consistency ECMP shortest path algorithms continue to use the maximum metric value in cases where the metrics advertised by adjacent nodes for a given link are different.

	Octet	Length
Type (29)	1	1
Length (6)	2	1
SPB Link Metric	3–5	3
Number PORTs	6	1
Port Identifier	7–8	2

Figure 28-9—SPB Link Metric sub-TLV

a) Type (8 bits) Value 29

b) Length (8 bits)

Total number of bytes contained in the value field.

c) SPB Link Metric (24 bits)

This indicates SPB Link Metric the administrative cost or weight of using this link as a 24-bit unsigned number. Smaller numbers indicate lower weights and are more likely to carry SPB traffic. Only one metric is allowed per SPB instance per link. If multiple metrics are required multiple SPB instances are required, either within IS-IS or within several independent IS-IS instances. If there are multiple links the metric for all links are the same.

d) Number PORTs (8 bits)

Number PORTs is the number of Port identifiers associated with this link.

e) Port Identifier (16 bits)

Port Identifier is the unique Port identifier comprising two parts, the Port Number and the Port Priority field (13.27.47).

28.12.8 SPB Adjacency Opaque ECT Algorithm sub-TLV

There are multiple ECT Algorithms defined for SPB, and in the future additional algorithms may be defined. The SPB Adjacency Opaque ECT Algorithm sub-TLV (Figure 28-10) may be included in an Extended IS Reachability TLV (type 22) or MT Intermediate System TLV (type 222) to carry new algorithm parameters associated with an adjacency. Multiple copies of this sub-TLV may be carried for different ECT Algorithms related to the adjacency.

	Octet	Length
Type (30)	1	1
Length	2	1
ECT-ALGORITHM	3–6	4
ECT Information	7–(Length+2)	variable

Figure 28-10—SPB Adjacency Opaque ECT-ALGORITHM sub-TLV

a) Type (8 bits) Value 30

b) Length (8 bits)

Total number of bytes contained in the value field.

c) ECT-ALGORITHM (4 bytes)

ECT-ALGORITHM is advertised when the Bridge supports a given ECT-ALGORITHM (by OUI or CID/Index) on a given VID.

d) ECT Information (variable)

ECT-ALGORITHM Information of variable length.

28.12.9 SPBV MAC address sub-TLV

The SPBV MAC Address sub-TLV (Figure 28-11) is carried in an MT-Capability TLV in an LSP. It should be used for advertisement of group MAC addresses in SPBV mode. Individual MAC addresses will normally be distributed by reverse path learning, but carrying them in this sub-TLV is not precluded. It has the following format:

		Octet	Length
	Type (4)	1	1
	Length	2	1
	reserved	3	2 bits
	S-R	3	2 bits
	SPVID	3–4	12 bits
MAC Address Tuple 1	T	5	1 bit
	R	5	1 bit
	reserved	5	6 bits
	MAC Address	6–11	6
...			
MAC Address Tuple n	T	(7n–2)	1 bit
	R	(7n–2)	1 bit
	reserved	(7n–2)	6 bits
	MAC Address	(7n–1)–(7n+4)	6

Figure 28-11—SPBV MAC Address sub-TLV

a) Type (8 bits) Value 4

b) Length (8 bits)

Total number of bytes contained in the value field.

c) SR bits (2 bits)

The SR bits are the service requirement parameter from MMRP. The service requirement parameters have the value 0 (Forward all Groups) (10.12.1.7) and 1 (Forward All Unregistered Groups) defined. However, this attribute may also be missing. So the SR bits are defined as 0 not declared, 1 Forward all Groups and 2 Forward All Unregistered Groups.

d) SPVID (12 bits)

This is the SPVID and by association Base VID and the ECT-ALGORITHM and SPT Set that the MAC addresses defined below will use. If the SPVID is not allocated the SPVID Value is 0.

NOTE—If the ECT algorithm in use is a spanning tree algorithm, this value should be populated with the Base VID.

e) T Bit (1 bit)

This is the Transmit allowed Bit for the following group MAC address. This is an indication that SPBV group MAC address with SPVID of source should be populated (for the Bridge advertising this Group MAC), and installed in the FDB of transit Bridges, when the Bridge computing the trees is on the corresponding ECT-ALGORITHM shortest path between the Bridge advertising this group MAC address with the T bit set, and any receiver of this group MAC address. A Bridge that does not advertise this bit set for a group MAC address should have no forwarding state installed for traffic originating from that Bridge on other transit Bridges in the network.

f) R Bit (1 bit)

This is the Receive allowed Bit for the following group MAC address. This is an indication that SPBV group MAC addresses as receiver should be populated (for Bridges advertising this group MAC address with the T bit set) and installed when the Bridge computing the trees lies on the corresponding shortest path for this ECT-ALGORITHM between this receiver and any transmitter on this group MAC address. An entry that does not have this bit set for an group MAC address is prevented from receiving on this group MAC address because transit Bridges will not install multicast forwarding state towards it in their FDBs or the traffic is explicitly filtered.

g) MAC Address (48 bits)

The MAC Address is either a group address or an individual address. When the MAC address is a group address it declares this Bridge as part of the multicast interest for this destination MAC address. Multicast trees can be efficiently constructed for destination by populating Group Address FDB entries for the subset of the SPT that connects the Bridges supporting the multicast address. This replaces the function of MMRP for SPTs. The T and R bits above have meaning if this is a group address. Individual addresses are populated only as if the R bit was set. (Note that individual addresses could also be learned normally.)

28.12.10 SPBM Service Identifier and Unicast Address (ISID-ADDR) sub-TLV

This sub-TLV (Figure 28-12) declares an individual B-MAC address and maps I-SIDs in the context of a B-VID to that B-MAC, allowing automatic creation of efficient group trees that are subsets of the SPT rooted at the node identified by that individual B-MAC address. In a symmetric ECT environment, the I-SIDs are mapped to a B-VID that is associated with a symmetric ECT Algorithm specifying the SPT Set. In ECMP the I-SIDs are mapped to a B-VID that is associated with the ECMP ECT Algorithm, which may specify a source rooted SPT or a shared tree for group addressed frames. Multicast trees can be selected per I-SID for maximum diversity. In the case of explicit trees, the I-SID is mapped to a B-VID allocated to one of the explicit ECT Algorithms (Table 45-1), and the B-MAC can be either an Individual MAC address or null. The null value indicates that the Backbone Service Instance Group address (26.4) is used by all sources of multicast traffic onto the given I-SID in (*,G) mode on one simple tree as specified in 45.1.5. This sub-TLV is carried in an MT-Capability TLV in an LSP.

a) Type (8 bits) Value 3

b) Length (8 bits)

Total number of bytes contained in the value field.

c) B-MAC Address (48 bits)

B-MAC Address is an individual MAC address on this Bridge. It may be either the single nodal address, or may address a port or any other level of granularity relative to the Bridge. In the case where the Bridge only has one B-MAC address this may be the same as the MAC address portion

		Octet	Length
	Type (3)	1	1
	Length	2	1
	B-MAC Address	3–8	6
	reserved	9	4 bits
	Base VID	9–10	12 bits
I-SID Tuple 1	T	11	1 bit
	R	11	1 bit
	Ts	11	1 bit
	reserved	11	1 bit
	Tie-Break Mask	11	4 bits
	I-SID	12–14	3
...			
I-SID Tuple n	T	(4n+7)	1 bit
	R	(4n+7)	1 bit
	Ts	(4n+7)	1 bit
	reserved	(4n+7)	1 bit
	Tie-Break Mask	(4n+7)	4 bits
	I-SID	(4n+8)–(4n+10)	3

Figure 28-12—SPBM Service Identifier and Unicast Address sub-TLV

SPB System Identifier of the Bridge. To add multiple B-MAC addresses, this sub-TLV shall be repeated for each additional B-MAC address.

Each individual MAC address has one or more I-SIDs that are associated with this address. In PBB terms this corresponds to a PIP B-MAC address. All B-MAC addresses that are used for individual MAC addresses and for the Sources of Group MACs shall be associated with at least one I-SID. This sub-TLV is initiated by IB-BEBs.

d) Base VID (12 bits)

The Base VID identifies the B-VID and by association the ECT-ALGORITHM and SPT Set that the I-SIDs defined below will use.

e) T Bit (1 bit)

This is the Transmit allowed Bit for the following I-SID. This is an indication that a group MAC Address Registration Entry (8.8.4) for this I-SID as source should be constructed and installed in the FDB of a Bridge, if the Bridge is on the corresponding ECT-ALGORITHM path between the Bridge advertising this I-SID with the T bit set and any receiver of this I-SID. A Bridge that does not advertise this bit or the Ts bit set for an I-SID should have no forwarding state installed for traffic originating from that Bridge on other Bridges in the network.

f) R Bit (1 bit)

This is the Receive allowed Bit for the following I-SID. This is an indication that a group MAC Address Registration Entry (8.8.4) for this I-SID as receiver should be constructed and installed (for Bridges advertising this I-SID with the T bit or Ts bit set) if a Bridge lies on the corresponding path for this ECT-ALGORITHM between this receiver and any transmitter on this I-SID. An entry that does not have this bit set for an I-SID is prevented from receiving on this group MAC addresses for this I-SID because Bridges will not install multicast forwarding state towards it in their FDBs.

g) Ts Bit (1 bit)

The Ts bit indicates that this I-SID source uses a shared tree for multicast frames. The group MAC address for this I-SID source is constructed using the Tie-Break Mask and the I-SID (27.15, Figure 27-6). A group MAC Address Registration Entry (8.8.4) is installed in any bridge on the

shared tree, selected by the Tie-Break Mask, between the advertising bridge and bridges that have the R bit set for the same I-SID. If both the T bit and Ts bit are set, the Ts bit takes precedence. This bit is ignored by ECT-ALGORITHM values in Table 28-1.

h) Tie-Break Mask (4 bits)

A 4-bit mask that is repeated to form a 64-bit mask used in selecting the low Bridge Identifier from a set of Bridge Identifiers. This selection process is used in multicast tree calculations to select a shared tree root Bridge and parent nodes in SPTs where equal cost paths are available. This field is ignored by ECT-ALGORITHMs in Table 28-1.

i) I-SID (24 bits)

I-SID is the 24-bit group service membership identifier. If two Bridges have an I-SID in common, intermediate Bridges on the unique shortest path between them will create forwarding state for the related B-MAC addresses. They will also construct multicast forwarding state using the I-SID and the Bridge's SPSourceID to construct a multicast DA. Each I-SID has a Transmit (T) and Receive (R) bit that indicates if the membership is as a Transmitter/Receiver or both (with both bits set). In the case where the Transmit (T) and Receive (R) bits are both zero, the I-SID is ignored (this forces a point-to-point capability that does not require Group address installation, but the advertised individual B-MAC address shall be processed and installed if required on the SPT). If more I-SIDs are associated with a particular B-MAC address than can fit in a single sub-TLV, this sub-TLV can be repeated with the same B-MAC address and MTID but with additional I-SID values. I-SID values can be in any order. Duplicate I-SIDs for a B-MAC address are allowed (within a sub-TLV, across two or more sub-TLVs, across two or more LSP fragments, or even across two or more LSPs). If the duplicates are in different B-VIDs, they are processed; otherwise, the T and R bits processed are the logical OR of the T and R bits of the two entries and it is processed as a single entry. (I-SID=0 is an exception that is always ignored, and allows a fast method to remove an I-SID without restructuring all the LSPs). Repacking an LSP (when I-SID=0 entries should be collapsed) can be done by moving entries from the high end into the empty I-SID=0 entries. To avoid outages temporary duplicates are allowed during this repacking and the entry further up in the LSP may later be removed without impact. The I-SID value 0x0000ff is reserved for SPB broadcast to all Bridges.

Item d), item h), and item i) are set to zero on transmit and ignored on receipt for SPBM symmetric ECT operation.

29. DDCFM operations and protocols

29.1 Principles of DDCFM operation

Data-driven and data-dependent connectivity fault management (DDCFM) comprises tools to facilitate the diagnosis and isolation of data-driven and data-dependent faults (DDFs) in Virtual Bridged Networks. This clause describes the functions of DDCFM and how they can be operated and managed. DDCFM is an extension to CFM specified by Clause 18 through Clause 22. As in the case of CFM, DDCFM capabilities can be used in networks operated by multiple independent organizations, each with restricted management access to others' equipment.

29.1.1 Data-driven and data-dependent faults (DDFs)

There are two broad types of faults in Virtual Bridged Networks that affect only certain frames or sequences of frames. Simple data-dependent faults are those that result in the repetitive loss or misdirection of each of those frames, independently of any other frames, and are usually the result of simple misconfiguration or of a failure to appreciate the consequences of a configuration option (installing protocol-specific filters, for example). Data-driven faults are more complex: the presence (or absence) of some data frames causes or contributes to the loss of other frames. While the services supported by Virtual Bridged Networks are conceptually data independent, the use of data-driven techniques enables enhanced service delivery. To give three examples: multicast frame filtering and consequent bandwidth saving is facilitated by Internet Group Membership Protocol (IGMP) snooping; stateful firewalls are used to protect users connected to managed services; and efficient allocation of frames to the individual links of an aggregation (IEEE 802.1AX Link Aggregation) is often based on spotting conversations by looking at frame data.

29.1.2 Basic principle to diagnose and isolate DDFs

The basic principle to diagnose DDFs is to isolate them to a small enough segment of the network, such as a Bridge Port, a member port of Link Aggregation Group (LAG) within a Bridge Port, or a LAN. Once DDFs are isolated, understanding the cause of the fault at this location becomes much easier.

The basic procedure to achieve isolation of a DDF is to divide the network into segments and determine whether certain data frames can traverse through each segment as expected. When a network segment is identified as faulty, the segment is further divided into smaller segments until a Bridge, a Bridge Port, or a member port of LAG within a Bridge Port is identified as not passing data frames as expected.

A DDF may not be apparent in the absence of live traffic (that is, when test data are used). DDCFM is designed to carry out the diagnosis while live traffic is being exchanged.

DDCFM facilitates diagnosis and consequent isolation of DDFs with the following two techniques: forward path test (FPT) and return path test (RPT).

29.1.2.1 Forward path test (FPT)

The goal of FPT, as depicted in Figure 29-1, is to determine whether specified data frames (frames associated with a service instance, or data frames with certain destination addresses or VID, etc.) can reach a particular location (which could be a Bridge Port, or a member port of LAG within a Bridge Port) without error. FPT's Reflection Responder (RR) (29.2.2) reflects the identified data frames (e.g., a service instance or selected data frames) to a specific target location, which could be an end station, a Bridge, or a test device. The data frames to be reflected can also be continued to their original destination(s). This option, called the Continue option throughout this standard, is to support testing of a data stream in a manner transparent to the application sourcing or sinking that data stream.

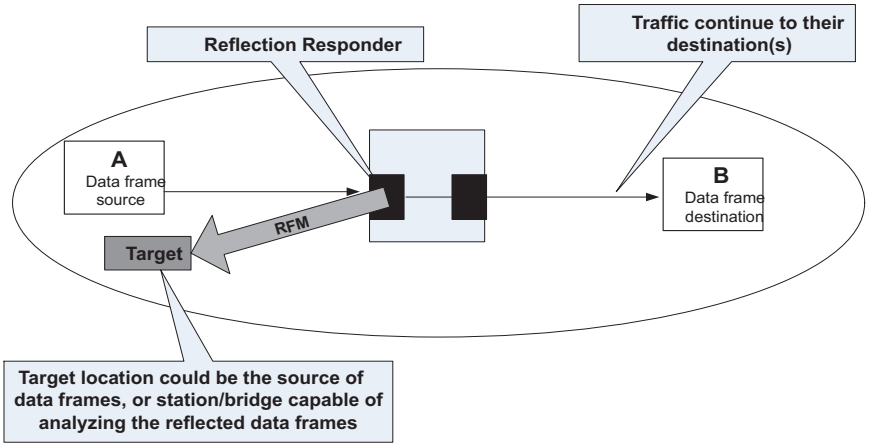

Figure 29-1—Forward path test (FPT)

FPT can be configured on ports where no MPs exist. However, when they are implemented within MPs or configured on ports with MPs, better fault isolation can be achieved. For example, if the target location does not receive the expected reflected data frames in the specified time span, it can send a LBM (21.7) to verify the connectivity between the Target location and the MP on which the RR (29.2.2) is configured. For a network that supports MEPs but not MIPs, FPT can be used to diagnose segment connectivity by configuring an RR on an intermediate node to encapsulate the received CCM in RFM format (29.4.2) and forward them to a target location.

The receiver at the target location records the reflected frames for examination by the operator and may also transfer the reflected frames to an analysis function. Some examples of target location analyzers are as follows: comparing the reflected frames with the original ones to verify if there are any errors, running a proxy application at the target location to simulate the handshakes as if those frames actually reach their original destinations, etc.

As in CFM (Clause 18 through Clause 22), a network operator can only set or activate FPT's RR within its own maintenance domain. At the customer's request, a network provider may use DDCFM to verify whether DDFs occur within its domain. FPT's RR (29.2.2) can only be created or activated by a network provider's own Network Management System via secure interface. Therefore, customers or other operators cannot set an FPT RR (29.2.2) in a maintenance domain that does not belong to them.

In order for intermediate Bridges and/or a target location to distinguish the reflected data frames from other traffic, each reflected frame is encapsulated with an RFM header. The RFM header added to the reflected data frame carries the same Maintenance Domain level associated with the RR, so that the reflected data frames, each encapsulated with a proper RFM header, are contained within the same Maintenance Domain. The target location has to be in the same maintenance domain to receive the RFMs.

Depending on the conditions specified for selecting data frames to be reflected, some conditions can cause large amount of data frames to be reflected. If there are multiple locations within a network reflecting a large number of data frames simultaneously, excessive traffic could be added to some segments of the network, which may impact network performance. To avoid excessive traffic being added to the network by an RR, this standard recommends only one RR be activated at a time within one maintenance domain.

FPT consists of RR configuration, the action to reflect identified data frames, and the analysis of the reflected data frames. The last step, i.e., analysis of the reflected data frames, is beyond the scope of this standard.

29.1.2.2 Return path test (RPT)

The RPT is to determine whether a flow of data frames can be sent without error from a specific location within a network to a station or stations specified by the destination_address associated with each of the frames under test. The RPT is achieved by an originating station encapsulating each frame of the flow under test with an SFM header, a DR (29.2.6) removing the SFM header, optionally placing its own MAC in the source_address field of the decapsulated data frames, and sending the data frames to a station or stations as specified by the destination_address field. By default, RPT's DR places its own MAC address in the source_address field of the decapsulated data frames before sending them out. However, a network operator can force a DR not to change the source_address field of the decapsulated data frame before sending it out to conduct special purpose testing.

The RPT allows a network operator to inject specific data frames into the network for testing purposes. To prevent one network operator from injecting traffic to other networks, it is necessary for the associated managed object to be created under secure mode and for SFM originator to be in the same Maintenance Domain as the MP on which DR is defined.

The Figure 29-2 illustrates a simple case of injected traffic from Node B to reach Node A. Multiple data frames can be injected and injected data frames could have different addresses or multicast addresses in their corresponding destination_address field.

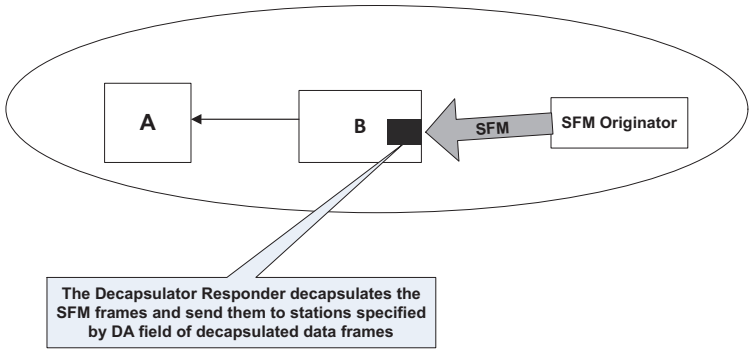

Figure 29-2—Return path test (RPT)

The RPT consists of the DR configuration, the sending of SFMs, the action to decapsulate and forward, and the analysis of the received data frames at their destination(s). The last step, i.e., the analysis of the received data frames at their destination(s), is beyond the scope of this standard.

29.1.2.3 Derived testing scenarios

FPT and RPT can be used together in various ways to achieve more sophisticated testing to diagnose and isolate DDFs. It is beyond the scope of this standard to elaborate different ways of combining FPT and RPT. This subclause only illustrates one example of using both FPT and RPT.

Figure 29-3 shows how to achieve segment fault isolation in the middle of a network using FPT and RPT together. By creating a DR and RR on two Bridge Ports in the middle of a network, a network operator can test whether the specified data frames can traverse through the segment. This type of testing is especially useful to diagnose DDFs out of firewall. This type of testing can also be used to diagnose a connectivity fault between two intermediate Bridge Ports (or two MIPs) by setting the RR filter (29.2.2.1) to the specified CCMs.

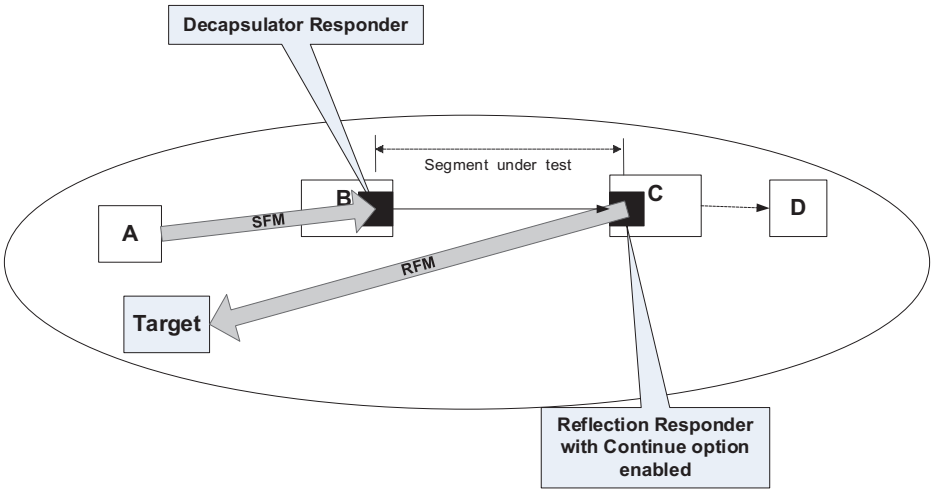

Figure 29-3—Combination of FPT and RPT

29.2 DDCFM Entity operation

This subclause specifies the following:

a) FPT RR
b) FPT RFM Receiver
c) RPT DR
d) RPT frames' SFM Originator

29.2.1 DDCFM implementation

The DDCFM protocol is performed by the RR, the DR, the RFM Receiver, and the SFM Originator. All of these entities are created and activated by operator commands. The operation of RR, DR, and SFM Originator are timer limited.

Both RFMs and SFMs are CFM PDUs and their format is described in 21.4 and 29.4. They are forwarded in the same way as regular CFM messages. An MEP at higher MD level shall drop the received RFMs and SFMs. An MEP at the same level shall process, but not forward, RFMs and SFMs received from its Active SAP, and shall drop RFMs/SFMs received from its Passive SAP. An MHF shall always forward RFMs/SFMs received from its SAPs and shall also process those at the same MD level received from its Active SAP.

The RR, RFM Receiver, DR, and SFM originator are CFM entities that are associated with a specific MD, enabling access only to the administrators of this MD. They can be placed at any point in the network that is bounded by any DoSAP of their corresponding MDs. Their relationship to MPs is guided by the MP component entities that the DDCFM entities also require. In particular, the RR does not require any of the MP's sub-functions (19.2 and 19.3) and correspondingly it is defined as an independent CFM shim. It can be placed at any Bridge Port bounded by the DoSAP of the RR's associated MD. It does not even require the EISS Multiplex Entity (6.17) or Backbone Service Instance Multiplex Entity (6.18). The same holds true for an SFM Originator. Note that both of them transmit CFM frames that are associated with a specific MA but the creation of these DDCFM entities themselves is not associated with an MA. This in practice means that one RR or SFM Originator can send RFMs or SFMs (respectively), which are associated with different MAs than the encapsulated frames. The other two DDCFM entities have a number of common subentities to the MPs. In particular, on top of their unique (MP) RFM Receiver and (MP) Decapsulator Responder state

machines, they require the functions provided by the Type Demultiplexer, Level Demultiplexer, and the OpCode Demultiplexer. In addition if the service is VLAN based, they also require the EISS Multiplex Entity. All of these make the implementation of the RFM receiver or the DR very simple in the case of an MP where they can reuse the MP component entities and provide the additional functions required by the MP RFM Receiver or MP Decapsulator Responder entities. Implementing these DDCFM entities on non-MPs would require all the previously mentioned MP subentities. Figure 29-5 shows an MP-independent RFM Receiver and Figure 29-6 shows an MP-independent DR. On the other hand, implementing these DDCFM entities on MPs would require only the addition of the MP Decapsulator Responder and MP RFM Receiver component entities in the MP architecture with the appropriate changes in the Opcode Demultiplexer as specified in 19.2 and 19.3.

29.2.2 FPT RR

The RR is a CFM protocol shim for filtering frames to be reflected, copying the filtered frames to the Passive SAP if the Continue option is set, and encapsulating each filtered frame with the RFM header (29.4.2). For an interface supporting DDCFM, an RR shim shall be allowed at EISS/ISS SAPs where MPs are allowed on the protocol stack shown in Figure 22-4, Figure 22-8, Figure 26-2, and Figure 26-8. By placing an RR shim on an aggregated port within a Bridge Port, the RR can reflect data frames from an member link of a LAG to test if specific data frames can go through the link.

The Figure 29-4 illustrates the component entities of an RR.

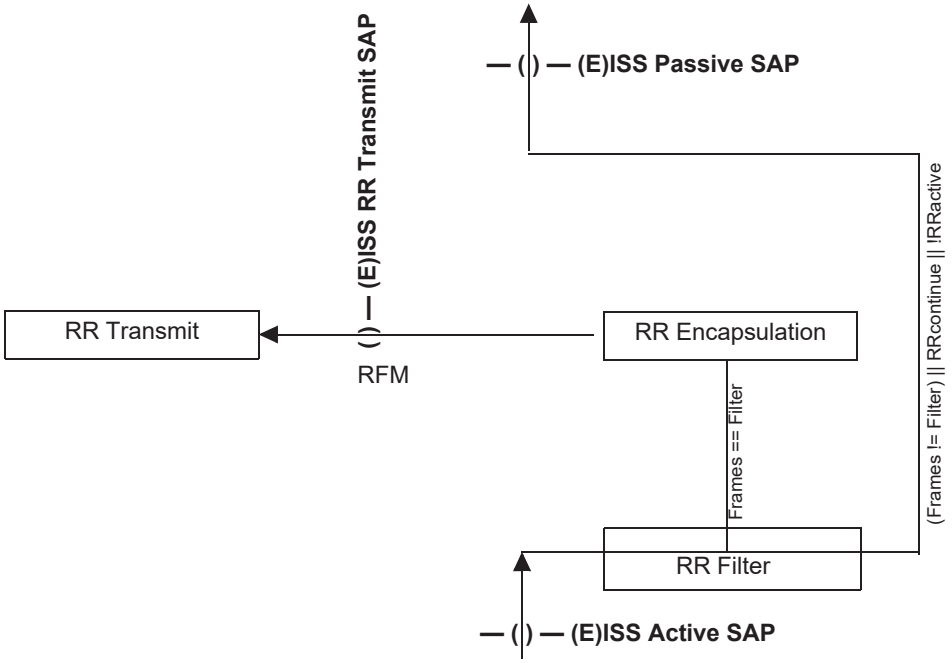

Figure 29-4—Detailed functions of RR

29.2.2.1 RR Filter

The RR Filter function within the RR filters frames from Active SAP that match the Reflection Filtering definition(s) [item b2) in 29.2.3]. When the RR is active and the sampling interval has expired, a frame that matches the Reflection Filter definition(s) is sent to RR Encapsulation to be reflected. A frame is passed to the Passive SAP when RR is not active, the frame does not match the Reflection Filter definition(s), or the Continue option is true.

To prevent data frames from being reflected multiple times within a network, RFM frames cannot be reflected. An RR Filter definition implicitly includes the condition of the OpCode in common CFM header not equal to RFM, in addition to all other conditions specified.

29.2.2.2 RR Encapsulation

The RR Encapsulation function within the RR is for encapsulating the filtered frame with the appropriate RFM header. If a sampling interval is specified, once a frame meeting the Reflection Filtering definitions is identified within one sampling interval, no more frames shall be encapsulated until the next sampling interval starts.

29.2.2.3 RR Transmit

RR Transmit identifies the egress port by querying FDB and forwards the RFM frames to the LOM entity of the identified egress port. The query uses the Reflection Target address [item b3) in 12.17.2.1.2] and the vlan_identifier associated with the RFM [item c) in 29.3.3.3]. If there is no vlan_identifier associated with the RFM, the PVID value of the port where RR is configured is used. If an egress port cannot be identified and the FloodingEnabled flag of the RR is true, then the RFM frame is sent to the LOM entity on every port associated with the VID set of the RFM frame. If the FloodingEnabled flag of the RR is false and an egress port cannot be identified, the RFM frame is dropped.

29.2.3 RR-related parameters

29.2.3.1 RR identification

An RR is identified by the interface upon which the RR is created, a Maintenance Domain that identifies the administrative boundaries, and a value indicating the direction (Up or Down) in which the RR is facing. The interface upon which the RR is created can be a Bridge Port or a member port of a LAG of a Bridge Port.

29.2.3.2 MA for RR

The primary VID associated with RR's MA is in the RFM emitted by the RR. When MA for an RR is set to 0, then the VID of the filtered frame are used in the corresponding RFM.

29.2.3.3 RR Filter definition

The RR Filter is for selecting data frames to be reflected. Multiple filters can be combined together by "&& (and)", "|| (or)", or "! (negation)" operations.

All Bridges supporting DDCFM shall support the following reflection filters (and may support additional Reflection Filters):

a) Reflect All—all frames are selected.
b) VLAN-based selection—all data frames associated with the specified VID are selected.
c) Destination address-based selection—all data frames with the specified destination address are selected.
d) Source address-based selection—all data frames with the specified source address are selected.
e) EtherType.

29.2.3.4 Sampling interval

The sampling interval controls the maximum rate at which frames can be reflected. If no sampling interval is set, then all frames that arrive while the RR is active and match the filter criteria are reflected. If a sampling interval is specified then the first matching frame that arrives during the interval is reflected, other matching frames arriving in that interval are not reflected.

29.2.3.5 Continue option

The Continue option [item b5) in 12.17.2.2.2] allows the selected data frames to be continued to their original destinations by making a copy of the selected frames to be reflected.

The Continue option is set to be true by default, which means that the selected data frames are branched to two directions—one direction to the RR Encapsulation function, and the other direction to the passive SAP. When the Continue option is set to be false, the selected frames shall only be forwarded to the RR Encapsulation function.

29.2.3.6 Duration for RR to remain active

Reflecting data frames back into network can create extra traffic in the network. To prevent this action running forever, a duration [item b7) in 12.17.2.2.2] is used to limit the maximum amount of time for the RR to be running. Operator can also specify the maximum number of frames to be reflected. Once activated, RR shall remain active until either its specified duration expires or the maximum number of frames reflected is reached, whichever comes first. An active RR can also be deactivated by operator command before its duration expires.

29.2.3.7 Truncation flag

If the received data frame causes the RFM encapsulated frame to exceed the Maximum Service Data Unit Size (6.5.8), either the data frame is truncated, or the data frame is split into two smaller frames and those two smaller frames are encapsulated by two separate RFM frames. If the Truncation flag is set to be true, the data frame shall be truncated to be encapsulated in one RFM.

29.2.4 Reflection Target and RFM Receiver

The Reflection Target is where the RFM encapsulated reflected frames are forwarded to. The RFM Receiver is a function running on a Reflection Target to pass the received RFMs to their corresponding analyzers.

The Reflection Target has to be within the same Maintenance Domain as the RR in order to receive the RFM encapsulated data frames.

When an RFM Receiver is defined on a Bridge interface that does not support MP, the RFM Receiver is implemented as a separate CFM entity, as depicted in Figure 29-5 for receiving RFMs from Active SAP. It requires a number of the component entities that are required by an MP. If the RFMs are associated with a VID-based MA, the RFM receiver needs to be placed in a demultiplexer SAP provided by an EISS multiplex entity (6.17).

29.2.5 RPT-related parameters

RPT configuration has two parts: one part is to configure SFM Originator and the other part is to configure DR.

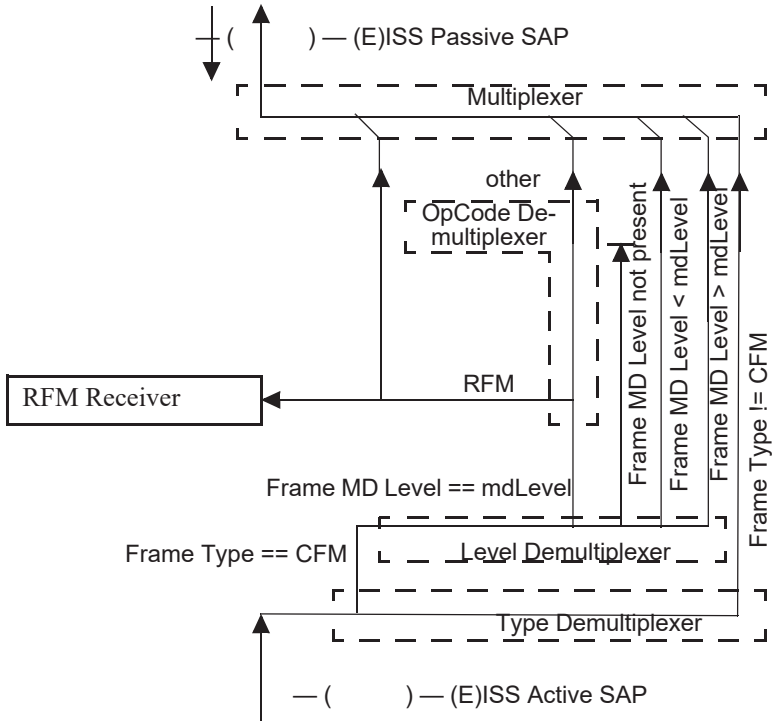

Figure 29-5—RFM Receiver on an non-MP

29.2.6 Decapsulator Responder (DR)

The DR decapsulates SFMs and sends the decapsulated frames toward destinations specified by the destination_address field of the decapsulated data frames. Under normal circumstance, the source_address field of the decapsulated frame is replaced by the DR's own MAC address to avoid confusing other Bridges' learning in the network. However, a network operator can enforce the DR not to modify the source_address field of the decapsulated frame for special purpose fault diagnosis. The DR configuration is specified in 12.17.4.1.

DR shim shall be allowed at EISS/ISS SAPs where MPs are allowed on the protocol stack shown in Figure 22-4, Figure 22-8, Figure 26-2, and Figure 26-8.

Multiple DRs can be created on one Bridge interface to receive SFMs at different MD levels or SFMs originated from different SFM Originators.

When an SFM is received by an active DR, it is examined for validity and discarded if invalid. If valid, the received SFM shall be decapsulated. The source_address field of the decapsulated frame is replaced by DR's own MAC address unless SourceAddressStayFlag is set. The modified frame shall be used to identify the egress port by querying the FDB. The query uses the destination_address and vlan_identifier values of the decapsulated data frame. If the decapsulated frame is untagged, the PVID value of the port where DR is configured is used. The Boolean FloodingEnabled flag of the DR indicates if the frame is to be flooded or discarded if an egress port cannot be identified by FDB. Figure 29-6 illustrates the detailed functions of DR. DR shim can be placed at any places where MPs are allowed on the protocol stack as shown in Figure 22-8.

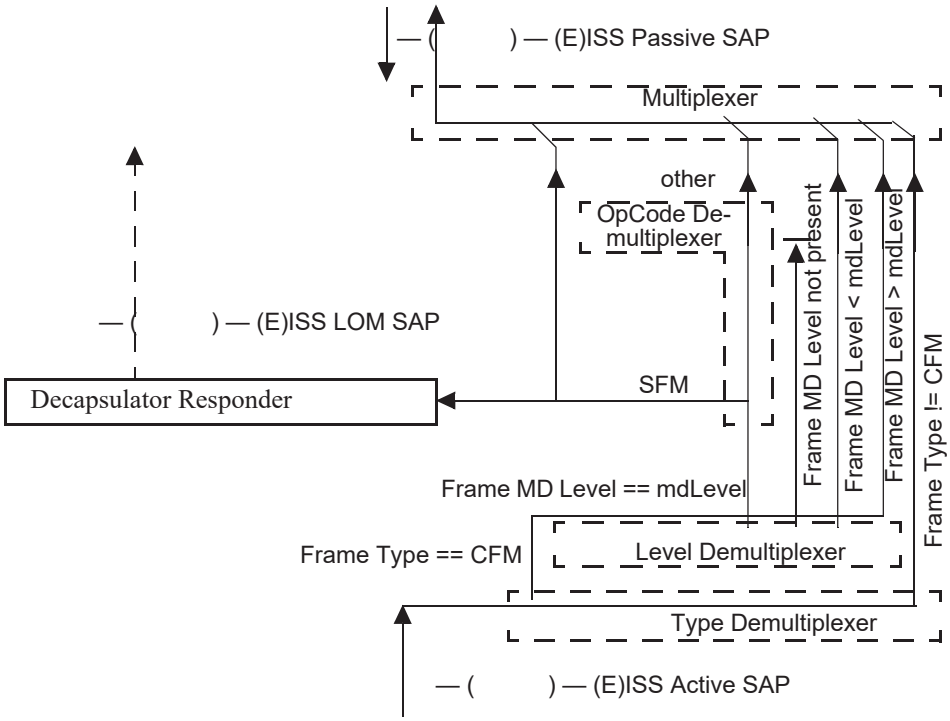

Figure 29-6—Return Path DR

29.2.7 SFM Originator

SFM Originator is for generating SFMs and sending the SFMs to the corresponding DR. Each SFM encapsulates one data frame. The SFM Originator configuration is specified in 12.17.5.1.

The Bridge interface on which SFM Originator is created does not have to support any MP. However, the SFM Originator has to be configured with the same Maintenance Domain level as the DR, so that the SFM can be forwarded to the DR. It is beyond the scope of this standard to address how SFMs are generated.

29.3 DDCFM protocols

This subclause specifies the DDCFM protocols in terms of a number of state machines, the variables and procedures associated with each machine.

29.3.1 RR variables

There is one instance of the following parameters per RR, except the nPendingRFMs variable, that is common to all RRs on the Bridge components (i.e., per Bridge component, but not per RR).

29.3.1.1 RRcontinue

A Boolean variable for the RR's Continue option [item b5) in 12.17.2.2.2] attribute.

29.3.1.2 nPendingRFMs

An integer value used to track the number of RFMs to be transmitted. nPendingRFMs is a variable that can be incremented by every RR's Encapsulation state machine and can be decremented by RR Transmit state machine.

nPendingRFMs is set to 0 when all of the RRs on the Bridge are deactivated.

29.3.1.3 dataReceived

dataReceived is a Boolean variable, which is set to true when there is a data frame received from (E)ISS, and set to false by the RR Filter state machine.

29.3.1.4 dataFrame

This variable is the data frame received from (E)ISS.

29.3.1.5 nFilteredFrameList

This variable keeps track of the number of filtered data frames to be reflected. This variable is incremented by RR Filter and decremented by RR's Encapsulation state machine.

29.3.1.6 filteredFrameList

This is a list of received data frames from RR Filter that have not been processed yet.

29.3.1.7 nextFilteredFrame

This variable copies the first one on the filteredFrameList to be reflected as RFM. Once a frame is copied to this variable, the frame is removed from the filteredFrameList.

29.3.1.8 RRtime

RRtime is the value of RR Duration (29.2.3.6).

29.3.1.9 RRwhile

RRwhile is a timer variable, which is initialized to RR Duration [item b7) in 12.17.2.2.2] when RR is activated and used by the RR Filter state machine to time out the active RR. RRwhile has granularity in seconds.

29.3.1.10 RRsampInt

RRsampInt is the sampling interval (29.2.3.4) during which the RR only reflects a maximum of one frame that meets the filter condition. When the sampling interval is not configured, RRsampInt is set to 0.

29.3.1.11 RRsampWhile

A timer variable used by RR Filter state machine to time out sampling interval.

29.3.1.12 RRmaxFrames

The maximum number of frames for RR to reflect after RR is activated [item b8) in 12.17.2.2.2]. Once activated, RR will stay active until either RRmaxFrames is reached or RRwhile (29.3.1.9) expires, whichever comes first. If RRmaxFrames is set to 0, the RR stays active until RRwhile (29.3.1.9) expires.

29.3.1.13 RRframeCount

A counter used by the RR's Encapsulation state machine to keep track of the number of data frames to be reflected. Once RRframeCount is equal to or greater than RRmaxFrames, RR is deactivated.

29.3.1.14 filterMatched

A Boolean variable that is set to true if the data frame received matches with the RR's filter conditions and false if the data frame received does not match the RR's filter conditions.

29.3.1.15 RRactive

RRactive is true when the corresponding RR is active and false otherwise.

29.3.1.16 nextRFMtransID

The value to place in the RFM Transaction Identifier field of the next RFM to be transmitted. nextRFMtransID is incremented by 1 by the RR's processRRencap() procedure with each transmission.

This variable is readable as a managed object [item b14) in 12.17.2.3.3].

29.3.1.17 maxDataTLVvalueSize

This is the maximum number of bytes allowed to be copied into Reflected Data TLV's value field in order to keep the RFM's SDU size not exceeding its Maximum Service Data Unit Size (MSDUS) (6.5.8).

The length of an RFM PDU is 12 octets (4 bytes for CFM header + 1 byte for End TLV(0) + 4 bytes Transaction Identifier + 3 bytes Reflected Data TLV Length/Type field) + the actual number of bytes of the reflected data frame. If there is no other optional TLV for the RFM data frame[41], then:

a) maxDataTLVvalueSize = MSDUS – (5 (CFM common header length) + 4 (Transaction Identifier) + 3 (Reflected Data Frame TLV Length/Type field)).

29.3.1.18 reflectedDataLength

This variable is to hold the value for the Length field of Reflected Data TLV (29.4.2.4).

29.3.2 RR Filter procedures

The following procedures are defined for the RR Filter state machine:

a) filterFrame()
b) forwardFrame()
c) loadFilteredFrameList()

29.3.2.1 forwardFrame()

This procedure passes the frame received to (E)ISS Passive SAP.

29.3.2.2 filterFrame()

filterFrame() is called when RRactive is true and there is a data frame received from EISS. This procedure performs the following steps:

a) If the received data frame from (E)ISS SAP meets the Reflection Filter definition(s), then returns true.
b) Otherwise, returns false.

29.3.2.3 loadFilteredFrameList()

This procedure adds the received frame to the filteredFrameList.

[41] Even though not required, implementers may choose to include other optional TLVs in RFM. If extra TLVs are included in a RFM, the maxDataTLVvalueSize has to be decremented by the number of bytes taken by the extra TLV.

29.3.3 RR Encapsulation procedures

The following procedures are defined for the RR Encapsulation state machine:

a) processRRencap()
b) splitFilteredFrame()
c) constructRFM()

29.3.3.1 processRRencap()

processRRencap() is called when RR is activated and filteredFrameList is not empty. There are two local variables in this procedure: DataFrame_1 and DataFrame_2, which are used when the filtered frame has to be truncated or split into two frames to be reflected.

processRRencap() processes the incoming data frame from the RR Filter as follows:

a) Set the reflectedDataLength variable to the length of the nextFilteredFrame.
b) If the value of reflectedDataLength is larger than the Bridge's maxDataTLVvalueSize (29.3.1.17), then call splitFilteredFrame (nextFilteredFrame, DataFrame_1, DataFrame_2) and then perform the following two steps:
    1) If Truncation flag is set, call constructRFM(TLV_type, maxDataTLVvalueSize, DataFrame_1), where the TLV_type is set to the "Truncated Data TLV" type value defined by Table 21-5.
    2) If the Truncation flag is not set, perform the following two steps:
        i) Call constructRFM(TLV_type, maxDataTLVvalueSize, DataFrame_1), where the TLV_-type is set to the "Data Part 1 TLV" type value defined by Table 21-5.
        ii) Call constructRFM(TLV_type, reflectedDataLength – maxDataTLVvalueSize, Data-Frame_2), where the TLV_type is set to the "Data Part 2 TLV" type value defined by Table 21-5.
c) Otherwise, call constructRFM(TLV_type, reflectedDataLength, nextFilteredFrame), where TLV_type is set to the "Data TLV" type value defined by Table 21-5.

29.3.3.2 splitFilteredFrame()

This procedure is called when the nextFilteredFrame causes the length of RFM's SDU size to be larger than the Maximum Service Data Unit Size (6.5.8). There are three parameters for this procedure:

a) nextFilteredFrame, which is an input to the procedure.
b) DataFrame_1, which contains the first maxDataTLVvalueSize number of bytes from the nextFilteredFrame.
c) DataFrame_2, which contains the remaining bytes from the nextFilteredFrame.

splitFilteredFrame() performs the following steps:

— Copy the maxDataTLVvalueSize number of bytes from the nextFilteredFrame to DataFrame_1.
— Copy the remaining bytes from the nextFilteredFrame to DataFrame_2.

29.3.3.3 constructRFM()

This procedure is to construct a RFM frame and increment the nPendingRFMs by 1. There are three parameters passed into this procedure:

a) TLV_Type, which could be 3 (i.e., Data TLV) (21.5.6), 9 (Truncated Data TLV) (21.5.1.1), 10 (Data Part 1 TLV), or 11 (Data Part 2 TLV).
b) TLV_Length, which is the length of the reflected data frame.
c) Data frame to be included in the TLV value field.

This procedure constructs the RFM (E)M_UNITDATA.request by the following steps:

d) Set the source_address parameter to the MP's or Bridge interface's own MAC address.
e) If the Reflection Target Address [item b4) in 12.17.2.2.2] is not specified, then source_address of the selected data frame is copied to the RFM's destination_address parameter; otherwise, Reflection Target Address is copied to the RFM's destination_address parameter.
f) Set the priority and drop_eligible parameters to the priority and drop_eligible attributes of the Reflection Responder managed object (12.17.2.2.2).
g) In a VLAN-aware Bridge, the primary VID associated with the RR's MA [item b1) in 12.17.2.1.2] is used as the vlan_identifier. If the RR's MA is set to 0, the vlan_identifier is determined by the following:
    1) If the RR is defined on an S-VLAN component, use the S-VID if the S-VID is present in the selected data frame; otherwise, use the PVID of the port where RR is configured.
    2) If the RR is defined on a C-VLAN component, use the C-VID if the C-VID is present in the selected data frame; otherwise, use the PVID of the port where the RR is configured.
h) Copy RFM OpCode to the RFM's OpCode Field.
i) Copy the RR's Maintenance Domain Level [item a) in 12.17.2.1.2] to the RFM's MDLevel field.
j) Copy the first parameter (TLV_Type) to the Reflected Data TLV Type field.
k) Copy the second parameter (TLV_Length) to the Reflected Data TLV Length field.
l) Copy the third parameter (Data frame) to the Reflected Data TLV value field.
m) Copy the nextRFMtransID to the RFM Transaction Identifier field. Increment nextRFMtransID by 1, wrapping around from $2^{32} - 1$ to 0.
n) Increment nPendingRFMs by 1.
o) Set the frame_check_sequence parameter to the unspecified value; sets the connection_identifier to null.

29.3.4 RR Transmit procedure

The following procedure is defined for the RR Transmit state machine:

a) xmitRFM()

29.3.4.1 xmitRFM()

xmitRFM() is called by the RR Transmit state machine. It queries the FDB in order to identify an egress port. The set of potential transmission ports, normally created by the Active Topology enforcement (8.6.1), is the set of all Bridge interfaces that are both in the active set of the vlan_identifier associated with the RFM, and that are in the Forwarding state for that vlan_identifier.

a) Query FDB using the RFM's destination_address field and vlan_identifier parameter values.
b) If an egress port is identified and the identified Egress port meets the following conditions:
    1) The Egress port does not have a Down MEP with higher MD level than the RFM's MD,
    2) The Egress port does not have an Up MEP with same or higher MD level as the received RFM's MD,
    1) then send an RFM EM_UNITDATA.request to the egress port's LOM SAP. Otherwise, drop the received RFM frame.
c) If an egress port cannot be identified:
    2) When the FloodingEnabled flag of the RR [item b7) in 12.17.2.1.2] is not set, drop the frame.

When the FloodingEnabled flag of the RR is set, send M_UNITDATA.request to the LOM's SAP of every forwarding port that meets the conditions 1) and 2) of item b) above.

29.3.5 RR-related state machines

29.3.5.1 RR Filter state machine

Figure 29-7 depicts the state machine for RR Filter.

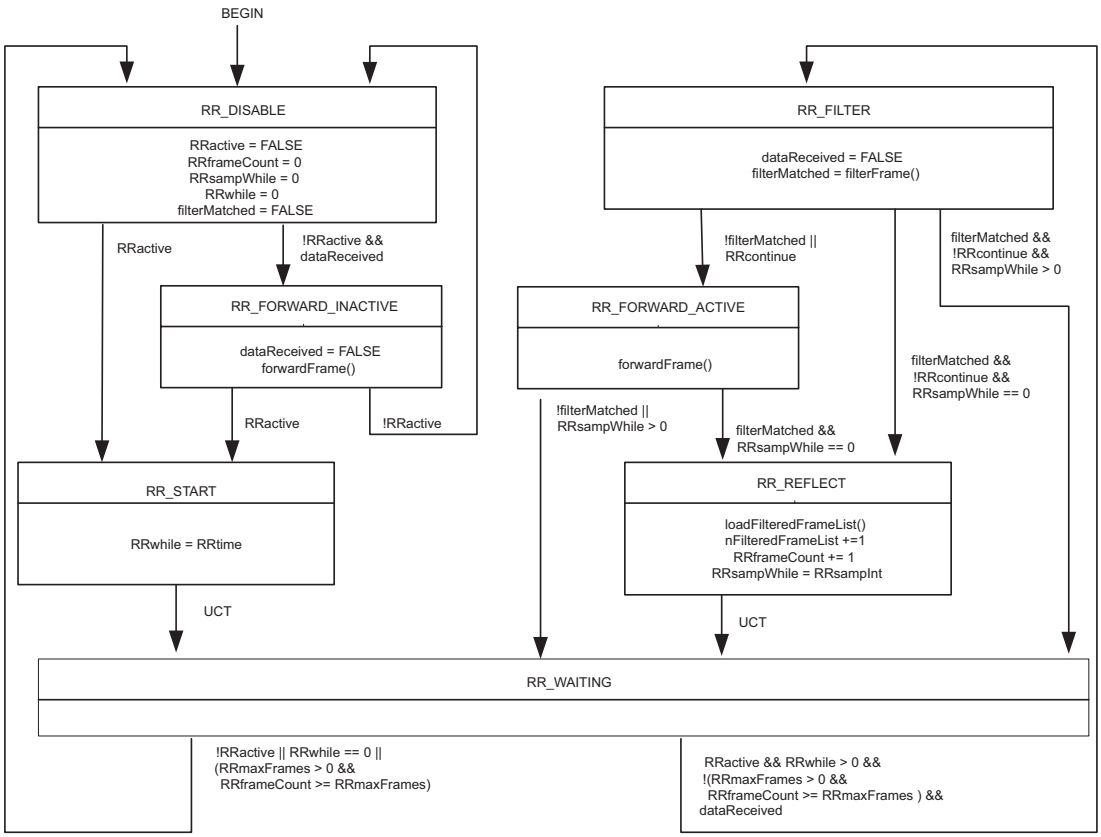

Figure 29-7—RR Filter state machine

Figure 29-8 describes the state machine for RR Encapsulation.

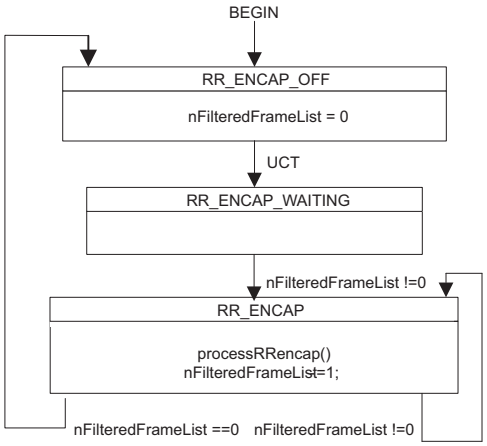

Figure 29-8—RR Encapsulation state machine

29.3.5.2 RR Transmit state machine

RR Transmit state machine (Figure 29-9) can be shared by multiple RRs activated on the Bridge.

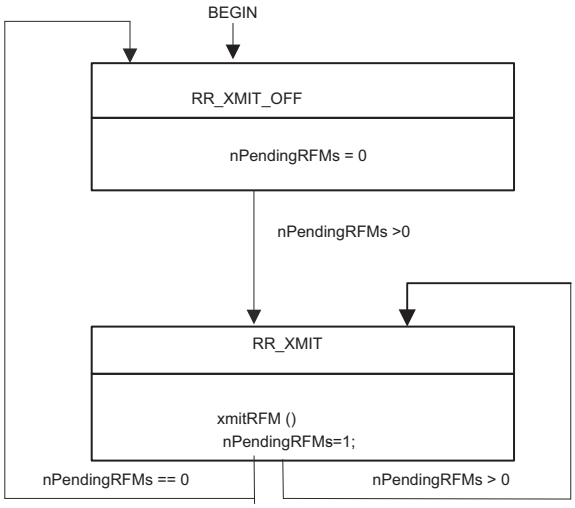

Figure 29-9—RR Transmit state machine

29.3.6 RFM Receiver variables

The following variables are local to the RFM Receiver state machine. There is one instance of these variables per RFM Receiver.

29.3.6.1 RFMreceived

RFMreceived is a Boolean variable, which is set to true by the MP OpCode Demultiplexer when an RFM is received, and cleared by the RFM Receiver state machine.

29.3.6.2 RFMPDU

RFMPDU is a record of the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the last RFM received by the MP OpCode Demultiplexer (19.2.7).

29.3.7 RFM Receiver procedure

The procedure listed in 29.3.7.1 and 29.3.7.2 is defined for the RFM receiver.

29.3.7.1 ReceiveRFM()

ReceiveRFM() procedure performs the following steps:

a) If the destination_address field of the received RFM does not match the RFM Receiver's MAC address, drops the frame.
b) Otherwise, pass the received RFMPDU to RFM Analyzer.[42]

Even though RFM Analyzer is out of the scope of this standard, RFM Analyzer has to be able to recognize the value in Reflected Data TLV (29.3.3.2), which could be:

— A whole data frame being reflected; or
— A truncated data frame being reflected; or
— The first portion of the data frame being reflected; or
— The second portion of the data frame being reflected.

If an RFM Receiver is configured on an MP and the RFM Receiver does not receive any RFMs within the expected time frame, it can send a LBM (21.7) to the MP on which the RR is defined to verify the connectivity to the MP. If there is no LBR received, ReceiveRFM() can report an alarm to the network administrator.

29.3.7.2 RFM Receiver state machine

Figure 29-10 describes the state machine for RFM Receivers.

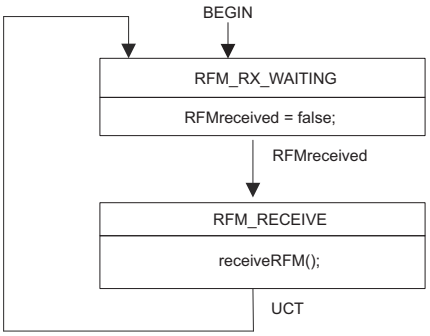

Figure 29-10—RFM Receiver state machine

[42] RFM Analyzer is out of the scope of this standard.

29.3.8 DR variables

There is one instance of the parameters listed in 29.3.8.1 through 29.3.8.7 per DR.

29.3.8.1 DRwhile

A timer variable used by the Decapsulator Responder state machine to time out the active DR. DRwhile has a granularity finer than or equal to 1 s.

29.3.8.2 DRtime

The time that the DR can remain active after its activation.

29.3.8.3 SFMPDU

SFMPDU is a record of the M_UNITDATA.indication or EM_UNITDATA.indication parameters of the SFM received by the MP OpCode Demultiplexer (19.2.7) when an SFM is received.

29.3.8.4 DRactive

DRactive variable represents the activation status of the corresponding DR. DRactive is set to true when the corresponding DR is activated and set to false when the corresponding DR is deactivated or its duration expires. When DRactive is false, all SFMs received by the Bridge interface are dropped.

29.3.8.5 SFMreceived

SFMreceived is set to true by the OpcodeDemultiplexer (19.2.7) when an SFM is received.

29.3.8.6 previousSFMtransId

previousSFMtransId variable keeps the value of SFM Transaction Identifier of the previously received SFM frame. The previousSFMtransId variable is initialized to zero when the DR is activated.

29.3.8.7 SFMsequenceErrors

SFMsequenceErrors variable keeps the total number of out-of-sequence SFMs received. SFMsequenceErrors is initialized to zero when the DR is activated.

29.3.9 DR procedures

The DR has the following procedures:

a) ProcessSFM()
b) DropSFM()

29.3.9.1 processSFM()

Called by the Decapsulator Responder state machine when an SFM is received and the DR is active. processSFM() processes the incoming SFM in SFMPDU as follows:

a) The SFM is examined for validity using the methods used for CFM as described in (20.46) and discarded if invalid.
b) If the destination_address of the SFM does not match the DR's own MAC address or the source_address of the SFM does not match with DR's SFM Originator [item b2) in 12.17.4.3.2], the frame is discarded.

c) If the SFM frame passes these tests, the frame carried in its Original Data TLV (29.4.3.4) is decapsulated to create an (E)M_UNITDATA.request as follows:
   1) The destination_address parameter is set to the destination_address of the frame in the Original Data TLV.
   2) If the SourceAddressStayFlag [item b1) in 12.17.4.3.2] is false, the source_address parameter is set to the DR's MAC address; otherwise, the source_address parameter is set to the source_address of the frame in the Original Data TLV.
   3) The vlan_identifier, priority, drop_eligible, and mac_service_data_unit parameters are set as follows:
      i) If the DR is configured on a port of an S-VLAN component, and the TPID of the frame in the Original Data TLV indicates the S-TAG, the vlan_identifier, priority, and drop_eligible parameters are taken from the corresponding values in the Tag Control Information (TCI) and the mac_service_data_unit is taken from the reminder of the frame following the TCI and excluding the last four octets (FCS).
      ii) If the DR is configured on a port of a C-VLAN component, and the TPID in the Original Data TLV indicates a C-TAG, the vlan_identifier, priority, and drop_eligible parameters are taken from the corresponding values in the TCI, and the mac_service_data_unit is taken from the remainder of the frame in the Original Data TLV following the TCI and excluding the last four octets (FCS).
      iii) Otherwise, the vlan_identifier is set to the PVID for the port on which the DR is configured, the priority is set to the priority of the SFM, the drop_elibible parameter is set to the value of drop_eligible for the SFM, and the mac_service_data_unit is taken from the frame in the Original Data TLV immediately following the source_address and excluding the last four octets (FCS).
   4) Sets the frame_check_sequence parameter to the unspecified value (IEEE Std 802.1AC).
   5) Sets the connection_identifier parameter to null.

d) ProcessSFM() queries the FDB using the destination_address and vlan_identifier parameters of the (E)M_UNITDATA.request. The set of potential transmission ports, normally created by the Active Topology enforcement (8.6.1), is the set of all Bridge Ports that are both in the member set of the vlan_identifier and that are in the Forwarding state for that vlan_identifier.
   1) If an Egress Port is identified, the decapsulated frame is carried to the related LOM SAP for transmission.
   2) If an Egress Port is not identified and the FloodingEnabled flag of the DR is set, the decapsulated frame is flooded to the LOM SAP of all forwarding ports in the VID set; otherwise, the frame is discarded.

e) If the received SFM is not the first frame received by the DR and the value of SFM Transaction Identifier field in the received SFM is not 1 greater than the value saved in the previousSFMtransId, increment SFMsequenceErrors by 1.

f) Set the value of previousSFMtransId to the value of the SFM Transaction Identifier field of the received SFM.

29.3.9.2 DropSFM()

Called by Decapsulator Responder state machine whenever the DR is not active in order to silently discard the received SFM frames.

29.3.10 Decapsulator Responder state machine

Once the DR is configured and activated by network administrator, it remains active until the configured timer expires or being deactivated by the network administrator (see Figure 29-11).

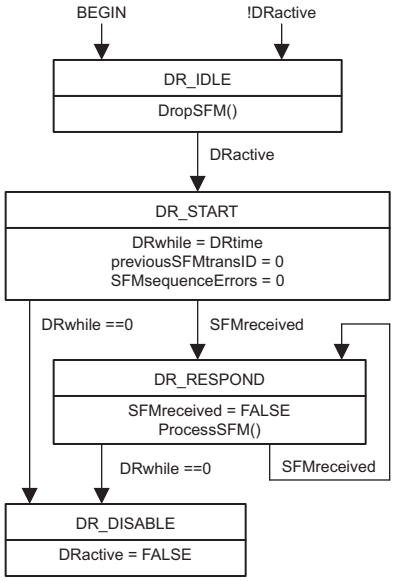

Figure 29-11—Decapsulator Responder state machine

29.4 Encoding of DDCFM PDUs

This subclause specifies the method of encoding DDCFM PDUs. The specifications include the following:

a) The format of RFM
b) The format of SFM

29.4.1 RFM and SFM Header

The RFM Header and SFM Header are same as the Common CFM Header defined by Table 21-2, with extra OpCodes defined for RFM and SFM (Table 21-3).

29.4.2 RFM format

The RFM format is shown in Table 29-1.

29.4.2.1 Flags

(1 octet) in RFM. The Flags field of the Common CFM Header for RFM is reserved for future use.

29.4.2.2 First TLV Offset

(1 octet) The First TLV Offset field of the Common CFM Header in a RFM is transmitted as 4.

Validation Test: The First TLV Offset field of the Common CFM Header in a RFM contains a value greater than or equal to 4.

Table 29-1—RFM format

Field	Octet
Common CFM Header	1–4
RFM Transaction Identifier	5–8
Reserved for definition in future versions of the protocol[a]	
Reflected Data TLV	First TLV Offset + 5
Additional TLV	First TLV Offset + 5 + Length of Reflected Data TLV
End TLV (0)	

[a] This field has 0 length in this version 0 of DDCFM. It is shown in order to stress that additional information can be present in future versions of DDCFM, and that a version 0 receiver ignores its contents, if present.

29.4.2.3 RFM Transaction Identifier

(4 octets) An RR copies the content of nextRFMtransID variable (29.3.1.16) to this field.

29.4.2.4 Reflected Data TLV

Reflected Data TLV in RFM is a Data TLV (21.5.6) to contain the reflected data frame. The Length field is the total octets of the reflected data frame.

The Type field of the Reflected Data TLV could be one of the following four values (Table 21-5):

a) Data TLV Type value, which is 3
b) Truncated Data TLV Type value, which is 9
c) Data-Part-1 TLV Type value, which is 10
d) Data-Part-2 TLV Type value, which is 11

29.4.2.5 Additional RFM TLVs

The following TLVs may be included in a RFM by each MP originating RFM (RR):

a) Send ID TLV (21.5.3)
b) Organization-Specific TLVs (21.5.2)

The Additional RFM TLVs may be placed in any order.

29.4.3 SFM format

The SFM format is shown in Table 29-2.

29.4.3.1 Flags

(1 octet) in SFM. The Flags field of the Common CFM Header for SFM is reserved for future use.

29.4.3.2 First TLV Offset

(1 octet) The First TLV Offset field of the Common CFM Header in an SFM is transmitted as 4.

Validation Test: The First TLV Offset field of the Common CFM Header in an SFM contains a value greater than or equal to 4.

Table 29-2—SFM format

Field	Octet
Common CFM Header	1–4
SFM Transaction Identifier	5–8
Reserved for definition in future versions of the protocol[a]	
Original Data TLV	First TLV Offset + 5
Additional TLVs	First TLV Offset + 5 + Length of Original Data TLV
End TLV (0)	

[a] This field has 0 length in this version 0 of DDCFM.

29.4.3.3 SFM Transaction Identifier

(4 octets) SFM originator may use this field to distinguish the order of SFMs sent. DR may use this identifier to check the order of the received SFMs.

29.4.3.4 SFM Original Data TLV

SFM Original Data TLV is a Data TLV (21.5.6) to contain the original data frame. The Length field is the total octets of the original data frame, including its destination_address, source_address, TPID, TCI, Length/Type, client data, pad, and FCS fields.

29.4.3.5 Additional SFM TLVs

The following TLVs may be included in an SFM by each SFM Originator:

a) Send ID TLV (21.5.3)
b) Organization-Specific TLVs (21.5.2)

The Additional SFM TLVs may be placed in any order.

30. Principles of congestion notification

Congestion notification comprises capabilities for detecting and mitigating queue congestion for selected classes of traffic in Virtual Bridged Networks. These capabilities can be used in networks with a bandwidth-delay product on the order of 5 Mbits or less in order to decrease the likelihood of frame loss for Congestion Controlled Flows (CCFs). As the geographical size, per-hop delay, and/or maximum hop count of a network grow, causing the bandwidth-delay product of the network to increase beyond this value, oscillations in buffer occupancy begin, and their amplitude increases gracefully with bandwidth-delay product. If the parameters controlling the algorithm are not adjusted accordingly and the sizes of the Bridges' buffers are not increased, frames are then likely to be lost due to congestion.

Congestion notification depends on the formation of a cooperating set of systems including VLAN Bridges and end stations to achieve the reduction in frame loss. By partitioning the Bridges' and end stations' resources, frames sourced or sunk by noncooperating end stations or Bridges can be carried with minimal contention with CCFs for those resources. Accordingly, congestion notification entities (Clause 31) are specified as shims that make use of and provide the ISS or EISS (IEEE Std 802.1AC, 6.8) at SAPs within the network. The operation of the congestion notification protocol is described in Clause 32, and the formats of the CNM and Congestion Notification TLV are described in Clause 33.

This clause provides the context necessary to understand the congestion notification protocol: how congestion controlled regions of networks are identified; how CCFs are identified and separated from other frames; and how congestion notification entities in Bridges and end stations operate.

This clause introduces the concepts essential to congestion notification as follows:

a) The problem and requirements on the solution are presented (30.1).
b) The basic principles of the Quantized Congestion Notification protocol (QCN) are presented, including descriptions of a CP that sends a CNM to a RP (30.2).
c) A CCF consists of frames, all with the same priority value, and all assigned to a single Flow queue and RP in the originating end station (30.3).
d) A Congestion Notification Priority Value (CNPV) is one of the eight priority values that has been configured exclusively for the use of CCFs in the congestion-aware systems of a Virtual Bridged Network (30.4).
e) A CN-TAG can be transmitted with every data frame in a CCF, and is returned in every CNM (30.5).
f) A CND is constructed as a subset of Bridges and end stations in a Virtual Bridged Network, all of which are configured to handle a particular CNPV, the resources of which subset are defended by the Bridges whenever the offered load exceeds the network capacity (30.6).
g) The relationship of Multicast data to congestion notification is explained (30.7).
h) The peering relationship of RPs and CPs in PBNs and PBBNs is explained (30.8).

30.1 Congestion notification design requirements

The congestion notification protocol, congestion notification algorithm (QCN), and supporting protocols specified in this standard meet requirements for the following:

— CCF and network performance.
— Limiting the implementation complexity, of both RPs and CPs.
— Not over-constraining the design of Bridged Networks using CCF.
— Facilitating interoperability, coexistence, and deployment into existing networks, and limiting the administrative effort associated with using CCF in a network.

NOTE 1—QCN is designed to operate over a wide range of conditions. This subclause (30.2) necessarily uses qualitative terms such as "low probability," "small," "stable," and "modest" (for brevity). The bibliography (Annex W)

provides references (Alizadeh et al. [B1]) to studies of QCN performance for various network and traffic configurations, using both simulation and a fluid model (see 30.3 for the necessary equations, and for network sizing recommendations).

The following performance requirements are met for s CCFs (30.3):

a) There is a very low probability of frame discard due to buffer overflow at a CP.
b) The average buffer occupancy at each CP that is a Current Congestion Point (CCP) for one or more CCFs is a small fraction of the bandwidth delay product, and largely independent of the number of CCFs, thus ensuring that loss avoidance does not result in large and fluctuating transit delays.
c) The buffer occupancy at a CCP has a low probability of underflow, i.e., of becoming empty and thus failing to use available bandwidth when an RP is rate limiting a CCF as a result of CNMs received from that CCP.
d) When multiple CCFs with a single CCP share that CCP, they obtain very nearly the same share of the bandwidth. When multiple CCFs have one or more CCPs in common they each obtain a share of bandwidth resources proportional to their share of contested resources.
e) The low probability of buffer overflow and underflow at a CCP is maintained for both small and large numbers of CCFs, and when CCFs or the load offered by a given CCF changes.
f) The bandwidth provided to each CP by its attached LAN will be used, at all times, i.e., if the CP's buffer is not empty it will transmit, given the available bandwidth. The fact that the bandwidth available to one CCF passing through a given CP can be constrained by another CCP will not reduce the bandwidth through that CP for other CCFs not sharing the CCP.

NOTE 2—The probability of frame loss in the absence of CCF naturally depends on the response of higher layer protocols to increasing transit delay, and the importance of avoiding loss on their response. Highly loss sensitive protocols typically lack loss avoidance mechanisms, and no such mechanisms are assumed in the analysis of QCN.

NOTE 3—Requirements a) through d) can be summarized by characterizing the performance of QCN as stable, responsive, and (proportionally) fair with respect to buffer occupancy processes. Requirements e) and f) demand that available resources are used, and that stability not depend on having a large number of slowly changing CCFs.

The following requirements limit the complexity and hence the cost of Bridge Port (CP) support for CCF:

g) The CCF state retained by each Bridge Port is fixed, and determined solely by the number of congestion management transmission queues (i.e., by the number of CPs, one per CNPV, up to a maximum of 7) and the per CP requirements of the congestion notification algorithm (QCN).
h) A CP does not retain any per CCF or per RP state, nor is it required to allocate any data frame passing through the CP to a CCF or an RP. All the information necessary for a CP to address a CNM to an end station, and for that end station to identify the CCF and RP from the CNM, is contained in each frame of a CCF.
i) The buffering required, at each CP, to avoid frame loss should be a small fraction of the network's bandwidth delay product.

The following requirements limit the complexity and hence the cost of end station (RP) support for CCF:

j) The CCF state retained by each end station for each congestion managed transmission queue, i.e., for each RP, is fixed.
k) The end station state requirements of QCN are determined solely by the number of RPs, and are independent of the number of CCFs and the number of CPs in the network.
l) The number of CCFs, the identification of each CCF, the allocation of transmitted frames to CCFs, and the allocation of CCFs to RPs is determined by each end station independently.
m) The end station is not required to transmit any additional frames, as a consequence either of transmitting or of receiving a frame for a CCF.
n) The CN-TAG for each CCF is independent of changes in RP state information.
o) The CCF protocol and QCN do not use any higher-layer protocol information carried in frames.
p) QCN calculations are simple and can be performed rapidly: i.e., the number of operations required to process each event is fixed, and all multiplications and divisions can be reduced to the use of

factors of 2 or the use of a fixed and small lookup table. An RP does not attempt to calculate control loop gains and delays and other, potentially rapidly changing CCF-dependent variables.

NOTE 4—A CP or an RP can retain additional state for the purposes of management, but this state is not required by the CCF protocol or QCN.

NOTE 5—An end station can use higher layer protocol information to decide whether a frame is to be allocated to a CCF, and to select a CCF.

The following requirements ensure that CCF does not over-constrain the design of the network, or limit the use of protocols that determine the active topology of the network:

q) RPs and CPs are unaware of the path taken by frames through the network, require no signaling from the network of changes in path, and take no exceptional action when paths change.

r) An RP does not assume that all frames that it transmits, or any identifiable subset of those frames such as those identified by the end station as belonging to a single CCF or transmitted to the same destination, are constrained to follow the same path through the network. An RP can transmit frames to many different destinations, and transmission to a given destination can be multi-path.

The following requirements support interoperability, facilitate deployment, and limit the administrative effort required to use CCF:

s) The boundaries of each CND are determined automatically.

t) The destination of a CCF can lie outside the transmitting end station's CND, and the destination end station can be unaware of the use of CCF within the CND. Incremental deployment of CCF is therefore possible.

u) The feedback provided in each CNM provides the receiving RP with the information needed to act on that CNM, and does not require the RP to know or interpret information about the sending CP.

v) PBBNs can be interposed into a CND, in order to reduce the number of MAC addresses leaned by Bridges in environments with large numbers of (perhaps virtual) end stations.

These requirements have a number of additional consequences for the design of QCN, including the following:

w) Additional mechanisms to determine round trip time are not required, as the algorithm is robust over its targeted range of round trip time.

x) QCN cannot regulate frame transmission by acknowledgments, as does Transmission Control Protocol/Internet Protocol (TCP/IP) [B18] [B19].

30.2 Quantized Congestion Notification protocol (QCN)

This subclause provides an overview of the baseline simulation of the QCN algorithm (Alizadeh et al. [B1]) used to develop this standard. This introduction provides no normative text. It will focus on the key features of the QCN algorithm, omitting the normative details given in the rest of this standard.

The QCN algorithm is composed of the following two parts:

a) **CP algorithm:** the mechanism by which a congested Bridge or end station buffer samples outgoing frames and generates a feedback message (CNM, 33.3, in this standard) addressed to the source of the sampled frame. The feedback message contains information about the extent of congestion at the CP.

b) **RP algorithm:** the mechanism by which a Rate Limiter (RL) associated with a source decreases its sending rate based on feedback received from the CP, and increases its rate *unilaterally* (without further feedback) to recover lost bandwidth and probe for extra available bandwidth.

30.2.1 The CP algorithm

A Bridge containing a CP is modeled as an ideal output-queued Bridge. The CP buffer is shown in Figure 30-1. The goal of the CP is to maintain the buffer occupancy at a desired operating point, Q_{eq}.[43] The CP computes a congestion measure F_b (defined below) and, with a probability depending on the severity of congestion, selects a frame from the incoming stream and sends the value of F_b in a feedback message to the source of the selected frame.

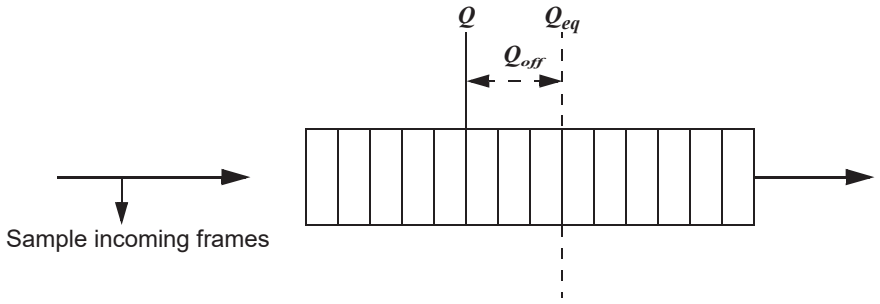

Figure 30-1—Congestion detection in QCN CP

Let Q denote the instantaneous queue size and Q_{old} denote the queue size when the last feedback message was generated. Let $Q_{off} = Q - Q_{eq}$ and $Q_{\delta} = Q - Q_{old}$.

Then F_b is given by Equation (30-1).

$$F_b = -(Q_{off} + wQ_{\delta}) \tag{30-1}$$

where w is a non-negative constant, taken to be 2 for the baseline simulation. The value of F_b is quantized to 6 bits before transmission, based on Q_{eq} and w.

The interpretation is that F_b captures a combination of queue size excess (Q_{off}) and rate excess (Q_{δ}). Indeed, $Q_{\delta} = Q - Q_{old}$ is the *derivative* of the queue size and equals input rate less output rate. Thus, when F_b is negative, the buffer is oversubscribed. When $F_b < 0$, Figure 30-2 shows the probability with which a congestion message is reflected back to the source as a function of $|F_b|$. The feedback message contains the value of F_b, quantized to 6 bits. When $F_b \geq 0$, there is no congestion and no feedback messages are sent.

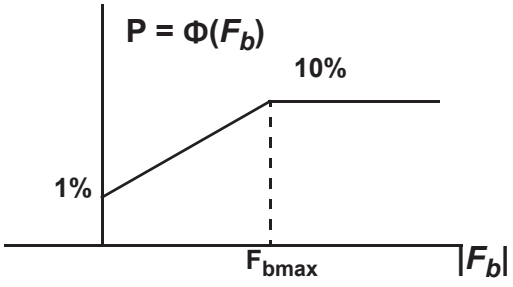

Figure 30-2—Sampling (reflection) probability in QCN CP as a function of $|F_b|$

[43] In simulation, setting Q_{eq} to 20% of the physical buffer size (150 000 octets) produced good results.

30.2.2 Basic RP algorithm

The RP is not given positive rate-increase signals by the network. Also, there are no acks at Layer 2 to trigger rate increases, Therefore, the RP requires a local mechanism to determine when, and by how much, the send rate is increased. Before proceeding to explain the RP algorithm, readers need the following terminology:

— **Current Rate (*CR*):** The transmission rate of the Rate Limiter (RL) at any time.
— **Target Rate (*TR*):** The sending rate of the RL *just before* the arrival of the last feedback message, and the new goal for the Current Rate.
— **Byte Counter:** A counter at the RP for counting the number of bytes transmitted by the RL. It triggers rate increases by the RL. See 30.2.2.2.
— **Timer:** A clock at the RP that is also used for triggering rate increases at the RL. The main purpose of the timer is to allow the RL to rapidly increase the rate when its sending rate is very low and bandwidth becomes available. See 30.2.3.

This clause now explains the RP algorithm assuming that only the byte counter is available. Later, how the timer is integrated into the RP algorithm is briefly explained. Figure 30-3 shows the basic RP behavior.

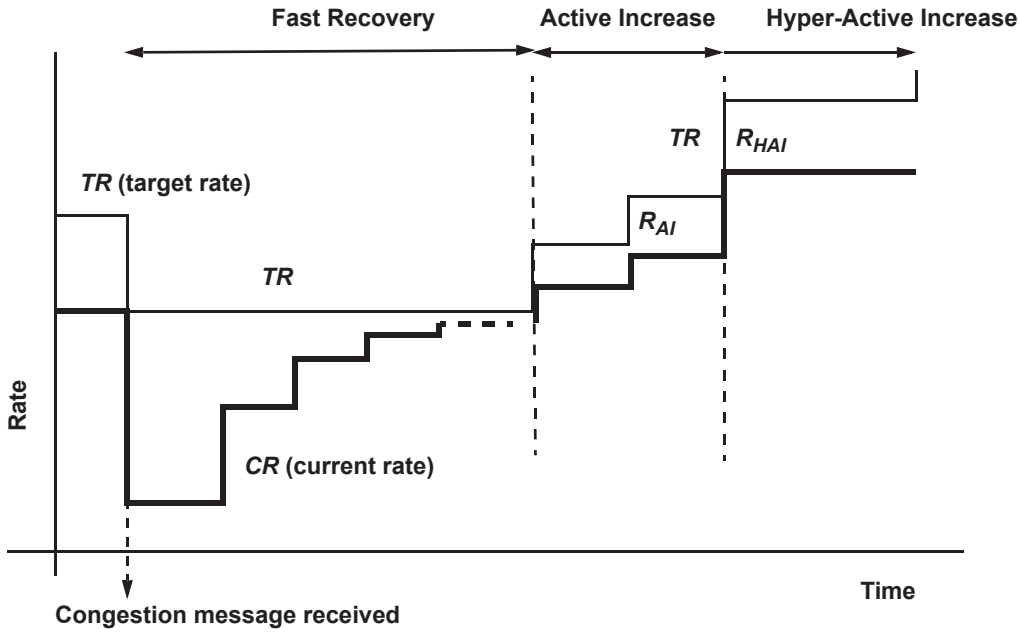

Figure 30-3—QCN RP operation

30.2.2.1 Rate decreases

Rate decreases occur only when a feedback message is received, in which case *CR* and *TR* are updated as follows in Equation (30-2) and Equation (30-3):

$$TR \leftarrow CR \tag{30-2}$$
$$CR \leftarrow CR(1 - G_d|F_b|) \tag{30-3}$$

where the constant G_d is chosen so that $G_d|F_{bmax}| = ½$, i.e., the sending rate can decrease by at most 50%.

30.2.2.2 Rate increases

Rate increases occur in two phases: Fast Recovery and Active Increase.

Fast Recovery (FR). The byte counter is reset every time a rate decrease is applied and the RP enters the FR state. FR consists of 5 cycles, each cycle equal to 150 kB of data transmission by the RL. The RP counts the cycles of the byte counter. At the end of each cycle, *TR* remains unchanged while *CR* is updated as follows in Equation (30-4):

$$CR \leftarrow \tfrac{1}{2}(CR + TR) \tag{30-4}$$

The cycle duration of 150 kB is chosen to correspond to the transmission of 100 frames, each 1500 bytes long. The idea is that when the RL has transmitted 100 frames and, given that the minimum sampling probability at the CP is 1%, if it has not received a feedback message then it may infer that the CP is uncongested. Therefore, it increases its rate as above, recovering some of the bandwidth it lost at the previous rate decrease episode. Thus, the goal of the RP in FR is to *rapidly recover* the rate it lost at the last rate decrease episode.[44]

Active Increase (AI). After 5 cycles of FR have completed, the RP enters the Active Increase (AI) phase where it probes for extra bandwidth on the path. During AI, the byte counter counts out cycles of 50 frames (this can be set to 100 frames for a less frequent probing). At the end of each cycle, the RL updates *TR* and *CR* as follows in Equation (30-5) and Equation (30-6):

$$TR \leftarrow TR + R_{\mathrm{AI}} \tag{30-5}$$
$$CR \leftarrow \tfrac{1}{2}(CR + TR) \tag{30-6}$$

where R_{AI} is a constant chosen to be 5 Mb/s in the baseline simulation.

30.2.3 RP algorithm with timer

Since rate increases using the Byte Counter occur at a frequency proportional to the current sending rate of the RL, when *CR* is very small, the duration of Byte Counter cycles when measured in seconds can become unacceptably large. Since the speed of bandwidth recovery (or responsiveness) is a key performance metric, a Timer was included in QCN.

The Timer functions similarly as the Byte Counter: it is reset when a feedback message arrives, enters FR and counts out 5 cycles of T ms duration (T is 10 ms long in the baseline), and then enter AI where each cycle is T/2 ms long.

The Byte Counter and Timer jointly determine rate increases at the RL as shown in Figure 30-4. After a feedback message is received, they each operate independently and execute their respective cycles of FR and AI. Together, they determine the state of the RL and its rate changes as follows:

a) The RL is in FR if *both* the Byte Counter and the Timer are in FR. In this case, when either the Byte Counter or the Timer completes a cycle, CR is updated according to Equation (30-4).
b) The RL is in AI if *only one of* the Byte Counter and the Timer is in AI. In this case, when either completes a cycle, *TR* and *CR* are updated according Equation (30-5) and Equation (30-6).
c) The RL is in HAI (for Hyper-Active Increase) if *both* the Byte Counter and the timer are in AI. In this case, the *i*th time that a cycle for either the Byte Counter or the Timer is completed, *TR* and *CR* are updated as shown in Equation (30-7) and Equation (30-8):

$$TR \leftarrow TR + i\mathrm{R}_{\mathrm{HAI}} \tag{30-7}$$
$$CR \leftarrow \tfrac{1}{2}(CR + TR) \tag{30-8}$$

where $\mathrm{R}_{\mathrm{HAI}}$ is constant set to 50 Mb/s in the baseline simulation (Figure 30-3). So the increments to *TR* in HAI occur in multiples of 50 Mb/s.

[44] The BIC-TCP algorithm [B65] has a similar Fast Recovery mechanism.

Thus, the Byte Counter and Timer should be viewed as providing the RL opportunities to increase the rate. Their state determines the state of, and hence the amount of rate increase at, the RL.

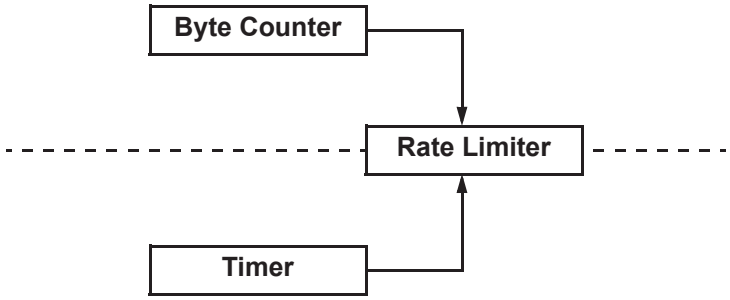

Figure 30-4—Byte Counter and Timer interaction with Rate Limiter

It is very important to note that the RL goes to HAI only after at least 500 frames have been sent and 50 ms have passed since the last congestion feedback message was received. This doubly ensures that aggressive rate increases occur only after the RL provides the network adequate opportunity (in frames sent for possible sampling) for sending rate decrease signals should there be congestion. This is vital to ensure the stability of the algorithm, and while optimizations can be performed to improve its responsiveness, in the interests of stability and simplicity, the baseline simulation (Alizadeh et al. [B1]) took no further optimization steps.

30.3 Congestion Controlled Flow (CCF)

A CCF consists of all of the frames passing through a single Flow queue (31.2.2.1) in an originating end station. Examples of CCFs include, but are not limited to,

a) The frames carrying data for a single User Datagram Protocol (UDP, IETF RFC 768, STD0006 [B17]) connection.
b) All of the frames generated by a particular process running in an end station.
c) All of the frames being transmitted by an end station that produce the same value when a hash computation is performed on the source and destination IP addresses, UDP vs. Transmission Control Protocol (TCP) selection, and source and destination UDP/TCP port numbers of the IP packets carried by those frames.
d) All of the frames passing through an RP that have the same destination_address parameter.
e) All of the frames being transmitted by an end station.
f) All of the frames passing through a Bridge Port sharing identical source_address, destination_address, and priority parameters.
g) All of the frames leaving a router that contain IP packets, and have identical values for their source and destination IP addresses, UDP vs. TCP selection, and source and destination UDP/TCP port numbers.
h) All of the frames with a certain value for the priority parameter.

All of the frames in a given CCF are sent with the same priority value, which is a CNPV (30.4).

Not all frames transmitted by an end station with an RP need be CCFs. Frames not belonging to CCFs bypass the Flow queues and RPs.

30.4 Congestion Notification Priority Value (CNPV)

A CNPV consists of one value of the priority parameter such that all of the Bridges' and end stations' ports in a Congestion Notification Domain (CND) are configured to assign frames at that value to the same CP and/or an RP. Different CNPVs correspond to classes of applications, or even single applications, such as interprocess communications or disk storage data, that have different requirements for such network resources as latency or bandwidth. Since there are eight values for the priority parameter, a single port in a Virtual Bridged Network can support as many as seven CNPV values; at least one value is required for best-effort traffic.

30.5 Congestion Notification tag (CN-TAG)

An end station may add a CN-TAG to every frame it transmits from a CCF. The CN-TAG contains a Flow Identifier field. The destination_address, Flow ID, and a portion of the frame that triggered the transmission of the CNM are the means provided by this standard by which a station can determine to which RP a CNM applies. How the station makes that determination is beyond the scope of this standard. The reasons for adding a CN-TAG include the following:

a) An end station can identify a particular flow within a CCF that triggered the CNM.
b) It can be simpler for the end station to use a Flow ID, rather than to parse the returned mac_service_data_unit of the original triggering frame, in order to identify either the RP or the particular flow.
c) Depending on the application, e.g., if fragmented IP datagrams are transmitted, it can be impossible to determine either the RP or the particular flow based solely on a returned mac_service_data_unit.

An end station that has only a single RP per CNPV, or that is able to identify the RP on the basis of the returned portion of the triggering frame, can omit transmitting the CN-TAG. The CP always returns a CN-TAG in a CNM with the triggering frame's Flow ID, or with a 0 Flow ID, if the triggering frame has no CN-TAG. The fixed format for the CNM minimizes the effort required of the CP to generate the CNM.

30.6 Congestion Notification Domain (CND)

In order for congestion notification to successfully control congestion in a Virtual Bridged Network, the managed objects controlling the congestion notification state machines in the Bridges and end stations in that network have to be configured with values that are appropriate to the characteristics of the CCFs generated by the applications that expect congestion controlled services. For example,

a) If frames that were not originated from an RP can enter a CP experiencing congestion, then the CNMs generated by that CP upon receipt of those frames cannot correct the problem, and congestion notification cannot operate correctly.
b) Congestion notification cannot operate correctly if a CP's configuration is inappropriate for the CCFs passing through it, or if priority values are regenerated in a manner that moves frames in and out of CNPVs.
c) Frames transmitted from an end station with a CN-TAG cannot be understood by an end station that is not congestion aware.

Congestion-aware Bridges therefore construct a CND, within which a particular CNPV is supported. A CND is a connected subset of the Bridges and end stations in a Virtual Bridged Network that are appropriately configured to serve a particular CNPV. This standard does not assume that every Bridge in a Virtual Bridged Network will be capable of congestion control, does not assume that every capable Bridge will be so configured, and does not assume that the subset of Bridges in a Virtual Bridged Network forming a CND that serves one CNPV will be the same subset that form a CND serving another CNPV.

CNDs can be created by configuring the Bridges and end stations in a network, or they can be created automatically, using an additional Type Length Value element, the Congestion Notification TLV (D.2.7), that this standard adds to the IEEE 802.1AB Link Layer Discovery Protocol (LLDP). Either way, every Bridge Port knows, for each CNPV, whether its neighbor(s) are or are not all configured with a matching CNPV.

NOTE—If CND boundaries are configured individually, rather than through LLDP, and there is an error in the configuration, there is a risk that frames not originating from RPs will pass through a CP, or that RP-originated frames will pass through a congested Port that has no CP. Either case can result in congestion that cannot be alleviated, with consequent excessive discarding of RP-originated data frames. In addition, such misconfiguration can result in a congestion-aware end station being unable to communicate with a congestion unaware end station, because the latter is receiving CN-TAGs that it does not understand.

Making each CND/CNPV independent, rather than making a single determination of neighbor capabilities based on whether all CNPVs are configured the same for all Ports attached to the LAN, allows a CND to be added to or removed from a network already using another CND, without disrupting the operation of the first CND.

30.7 Multicast data

Although control of multicast streams is not an object of this standard, and no simulations or experiments involving multicast data were utilized in the writing of this standard, the transmission of multicast data through a CCF is not prohibited. Some applications primarily send unicast data, but send occasional multicast frames for purposes such as discovery. Transmission of multicast data has been allowed in order to allow well-designed applications using a very small percentage of multicast traffic to operate on a CNPV.

Multicast streams are often sent to multiple destinations along multiple paths through the network, and a unicast stream normally travels along a single path. Therefore, a multicast stream is more likely to encounter any congested ports that exist in a network than is a unicast stream. The consequences of sending multicast streams on a CCF include the following:

a) The RP could limit the CCF to the rate of the slowest (most congested) path taken by the multicast.
b) The chances of unintended fate sharing are higher in a CCF that included multicast streams. That is, a multicast stream is more likely to unnecessarily slow down a unicast stream sharing the same CCF than one unicast stream is likely to slow down another.

30.8 Congestion notification and additional tags

The transmission of a CNM from a CP to an RP makes the CP and RP peer entities in the sense discussed in IEEE Std 802.1AC. An example of this peering relationship for a VLAN Bridged Network is illustrated in Figure 30-5, with the CP-RP relationship shown by a heavy dashed line.

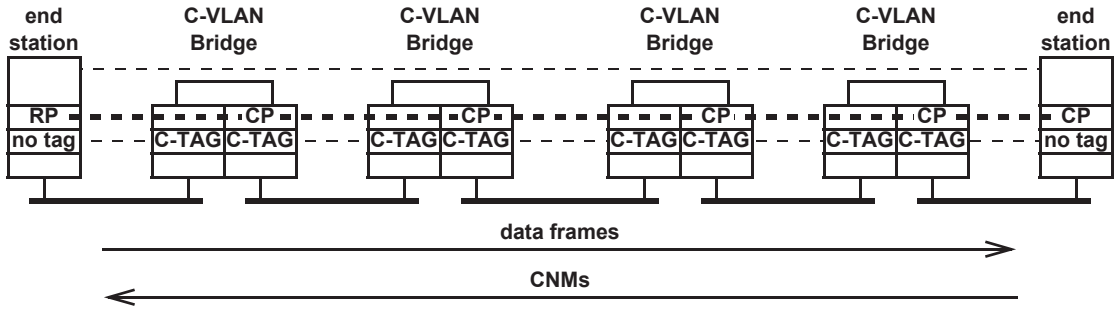

Figure 30-5—CP–RP peering in VLAN Bridged Network

PBBs (Clause 25) could be used in a data center environment, in order to reduce the number of MAC addresses that have to be learned in the core of the network. The I-component (5.7) of a PBB adds and removes I-TAGs (9.7) on data frames. However, as illustrated in Figure 30-6,[45] adding an I-TAG to a data frame by an I-component impairs the ability of a CP in the core of that network to return a CNM that will be meaningful to the originating end station. The following two difficulties follow from the fact that a CP in a BCB is not a peer of the RP in an end station:

a) The BCB CP cannot parse the I-TAG and C-TAG, which is necessary in order to find the RP's MAC address and the data frame's CN-TAG, in order to build an I-TAG-encapsulated, CNM addressed to the RP.
b) There is no MAC address available to the BCB CP that would be a valid source_address in the CNM when received by the RP.

In order to provide the benefits of PBBNs or other hierarchical bridging technologies to the data center environment, an interworking function (32.16) is defined to allow core CPs to peer with end stations.

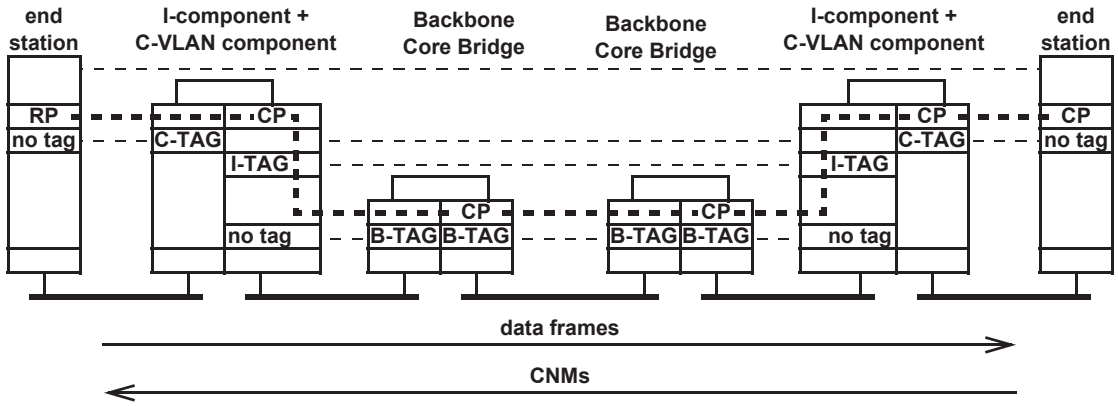

Figure 30-6—CP–RP peering in PBBN

[45] In the configuration chosen for illustration for the data center environment in Figure 30-6, each S-VLAN component of an I-components is, in effect, a Provider Bridge (5.10). That is, each CNP in an I-component is virtualized and multiplied, and connected to a corresponding virtual PEP of a C-VLAN component offering a single CEP facing the end station. This offers a C-TAG interface to the end station, without incurring the burden of an additional layer of S-TAGs.

31. Congestion notification entity operation

This clause specifies the following:

a) The architecture of the CP in the Forwarding Process in a congestion-aware Bridge component or end station (31.1).
b) The architecture of a CP and an RP in a congestion-aware end station (31.2).

NOTE—Clause 30 introduces the principles of congestion notification operation and the network architectural concepts that support it. Clause 32 specifies the protocols operated by entities defined in this clause. Clause 33 specifies the encoding of the PDUs used by congestion notification.

The models of operation in this clause provide a basis for specifying the externally observable behavior of congestion notification, and are not intended to place additional constraints on implementations; these can adopt any internal model of operation compatible with the externally observable behavior specified. Conformance of equipment to this standard is purely in respect of observable protocol.

31.1 Congestion-aware Bridge Forwarding Process

Figure 8-12 illustrates the details of the Bridge Forwarding Process. Figure 22-1 shows a different view of those details, rearranged so that those entities of the Forwarding Process that are concerned only with a single Bridge Port can be put in the proper relationship to entities such as CFM shims. Figure 31-1 shows only the queuing functions of Figure 22-1, as modified for a congestion-aware Bridge. Two new entities are added for the congestion-aware Bridge: the CP (31.1.1) and the CP ingress multiplexer (31.1.2).

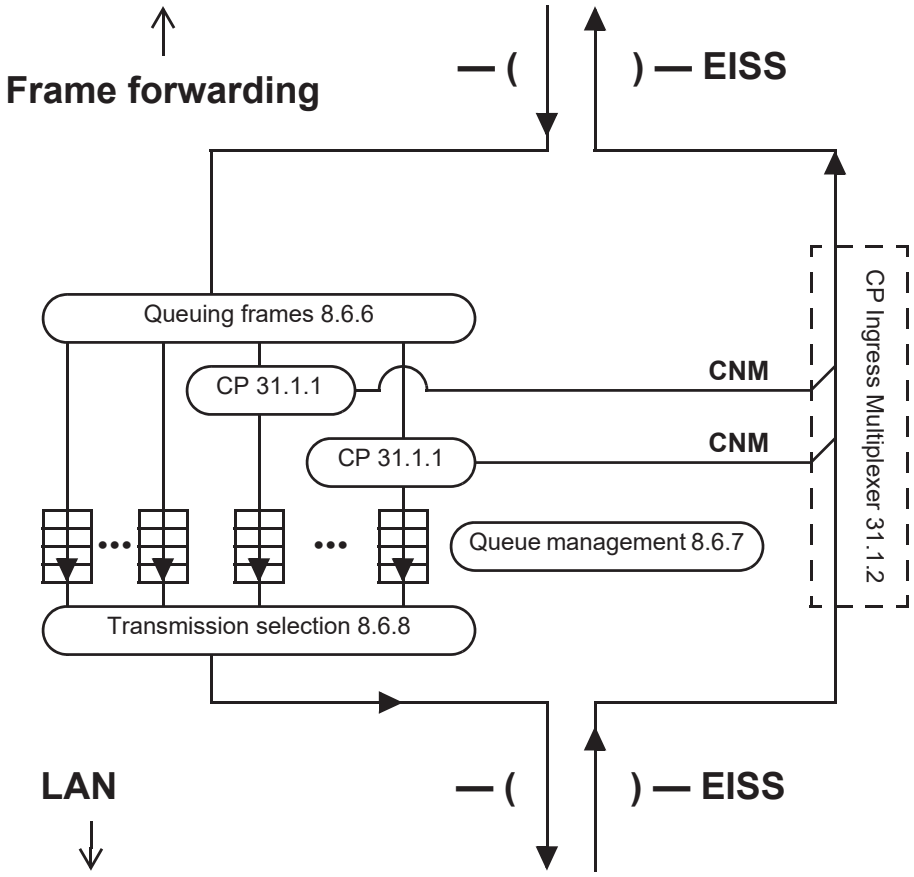

Figure 31-1—CPs and congestion-aware queues in a Bridge

31.1.1 Congestion Point (CP)

As described in 32.8 and 32.9, based on the state of its internal variables, and a frame given the CP by the Queuing frames entity (8.6.6) in an EM_UNITDATA.request (parameters) (32.9.3), a CP either inserts the frame into its attached queue or discards the frame, and can generate a CNM, based on the frame. Discarded frames are counted in the variable cpDiscardedFrames (32.8.12). Frames successfully queued are counted in the variable cpTransmittedFrames (32.8.13). Any CNM generated is passed to the CP ingress multiplexer (31.1.2, Figure 31-1) or Flow multiplexer (31.2.4, Figure 31-2) for transmission back to the RP that sourced the frame.

Congestion notification does not operate correctly if frames not belonging to a CCF are allowed to pass through a CP. The CND operations (32.1) help to ensure that the only frames passing through a CP belong to CCFs.

The CP shall remove the CN-TAG from every frame passing through it with a priority value (a CNPV) for which the port on which the CP resides is acting in cptEdge or cptInterior CND defense mode.

The functions of Figure 22-1 could be implemented in different ways than that illustrated, without altering the externally observed behavior of the conformant equipment. For example, the CP could pass a copy of the output frame triggering a CNM to a function in the higher layer interfaces of a Bridge, which in turn, could generate the CNM. However, in order to provide a management interface that is useful over a wide range of implementations, the following provisions are made:

a) CNMs generated on a Bridge Port are not counted in the Frames Received [item a) in 12.6.1.1.3] or Octets Received [item b) in 12.6.1.1.3] counters.
b) CNMs generated on one Bridge Port are counted, as are ordinary data frames, on the Bridge Ports (if any) on which they are output.

If a Bridge supports the dot1agCfmVlanTable or the ieee8021CfmVlanTable, its CPs transmit each CNM to the Primary VID associated with the vlan_identifier of the frame triggering the CNM's transmission.

31.1.2 CP ingress multiplexer

Inserts the CNMs generated by the CPs (31.1.1) among the frames received from the LAN.

31.2 Congestion-aware end station functions

Figure 31-2 illustrates the architecture of the queue functions of a congestion-aware end station. These functions offer a service to higher layers through a single instance of the ISS or EISS, and utilize an instance of the ISS or EISS to connect to the lower layers. The Output flow segregation function is presumed to exercise control over the higher layers' ability to present frames for transmission through the ISS or the EISS, and the Reception selection function to control the flow of frames to the higher layers, by means of additional parameters local to this instance of the ISS or the EISS and/or locally significant LMI parameters (IEEE Std 802.1AC), neither of which are specified by this standard.

In Figure 31-2, the outbound queue block, in the lower left of Figure 31-2, is exactly the same as the output queues in a Bridge Port that is not congestion aware, as illustrated in Figure 22-1.

The remaining entities illustrated in Figure 31-2 are those that are peculiar to a congestion-aware end station, and are further described in the following subclauses.

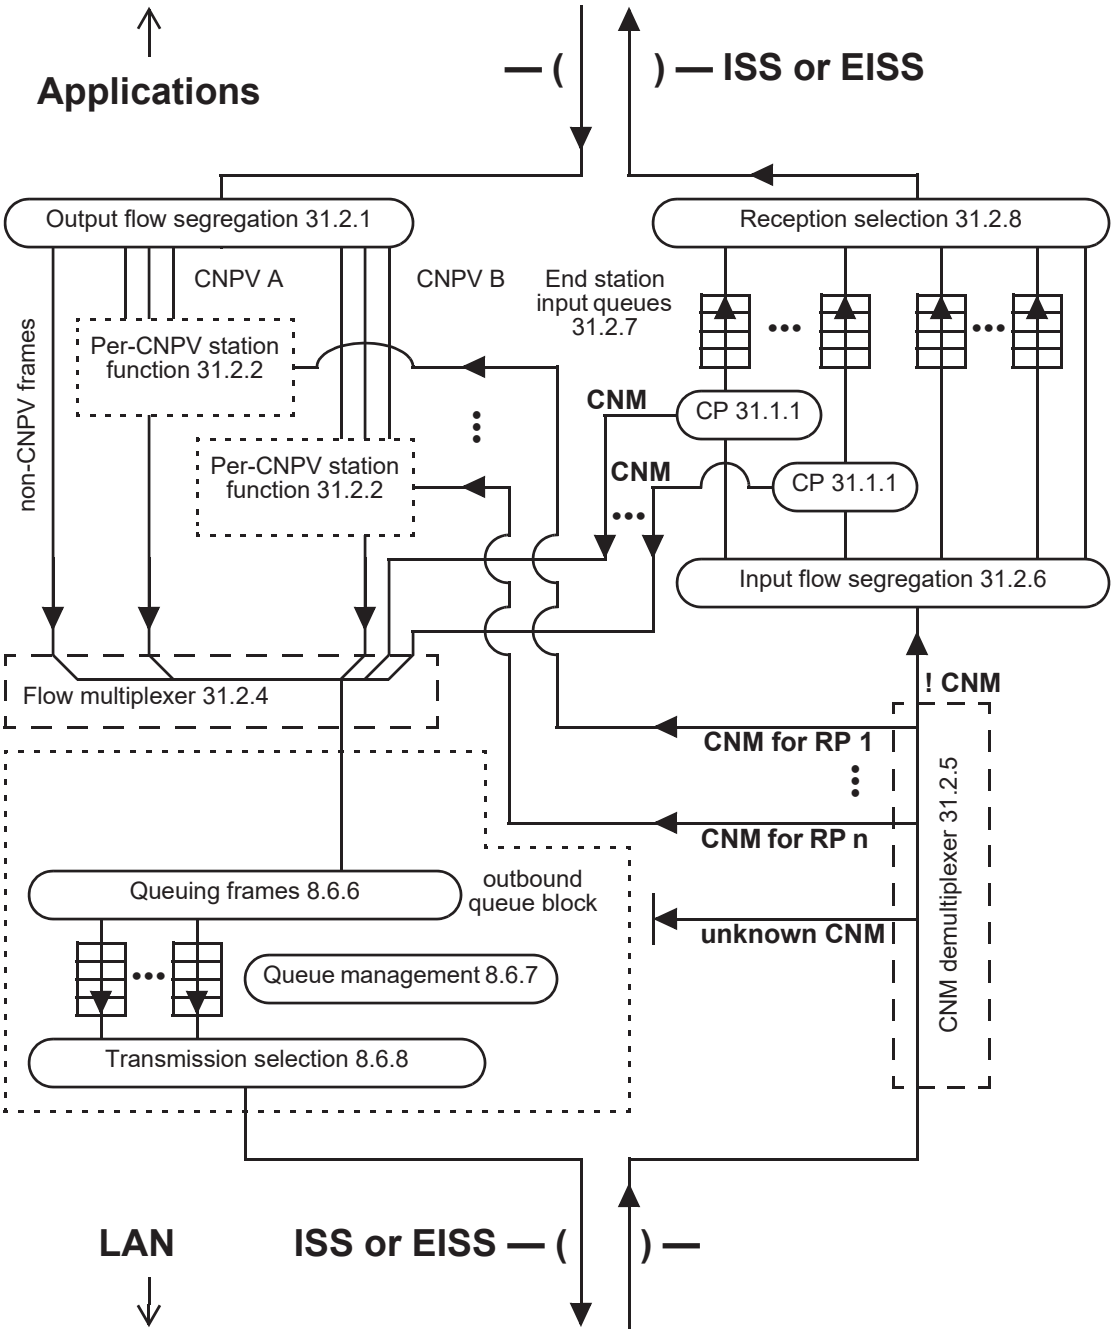

Figure 31-2—Congestion-aware queue functions in an end station

31.2.1 Output flow segregation

For each frame received from the upper layers for transmission, the Output flow segregation entity:

a) Assigns the frame a priority parameter based on the priority presented from the upper layer and/or upon other criteria, unspecified by this standard.
b) Determines, using priority value and the Flow Select Database (31.2.3), to which Flow queue, if any, the frame is to be assigned.
c) If the frame is not assigned to any Flow queue (the frame's priority is not a CNPV), passes the frame directly to the Flow multiplexer entity (31.2.4).
d) If the frame is assigned to a particular Flow queue (the frame's priority is a CNPV), enqueues the frame in the selected Flow queue.
e) For frames that are assigned to a Flow queue, depending on the state of the Flow queue to which the frame is assigned, and through means unspecified by this standard, can influence the higher layers' presentation of further frames to the Output flow segregation entity.

The Output flow segregation entity never discards a frame. Every frame presented to it is either passed to the Flow multiplexer entity (31.2.4) or stored in a Flow queue, as described previously. This standard assumes that the Output flow segregation entity can apply means, unspecified by this standard, to prevent the upper layers from offering a frame that should be stored in a Flow queue, but for which the Flow queue has insufficient resources.

The default configuration for an end station shall have a single Flow queue per CNPV. An end station may support additional Flow queues, or support more than one CNPV with a single Flow queue.

NOTE—Requirements for a default configurations do not imply that explicit action via SNMP is required to change from the default. For example, managed objects in an end station can be adjusted by an application program.

If the Output flow segregation function in an end station can change its method for assigning frames to Flow queues, it shall not do so in a manner that impairs the ability of any compliant CP implementation to throttle the data from the sourcing end station, and shall not materially increase the likelihood of misordered frame transmissions in a manner that adversely impacts the higher layers' functions.

31.2.2 Per-CNPV station function

There is one Per-CNPV station function on each Port of a congestion-aware end station for each priority value that is a CNPV. All of the frames passing through a Per-CNPV station function have the same CNPV priority parameter value.

As illustrated in Figure 31-3, each Per-CNPV station function is composed of the following entities:

a) One or more Flow queues (31.2.2.1).
b) One or more RPs (31.2.2.2), each associated with exactly one Flow queue, each comprising:
    1) A RP state machine (31.2.2.3) for each RP.
    2) A Rate Limiter (31.2.2.4) for each RP.
c) One Flow Selection function (31.2.2.5).

31.2.2.1 Flow queue

A Flow queue is a first-in-first-out queue of frames, all for the same CNPV. An Output flow segregation entity selects the Flow queue into which a given frame is inserted, and an RP determines when a frame is removed from a Flow queue.

NOTE—The Flow queue is a notional convention used to unambiguously describe the behavior of the RP. An end station can implement the Flow queue without explicitly storing frames in a queue, based on its knowledge of the state of the higher-layer applications supplying the frames.

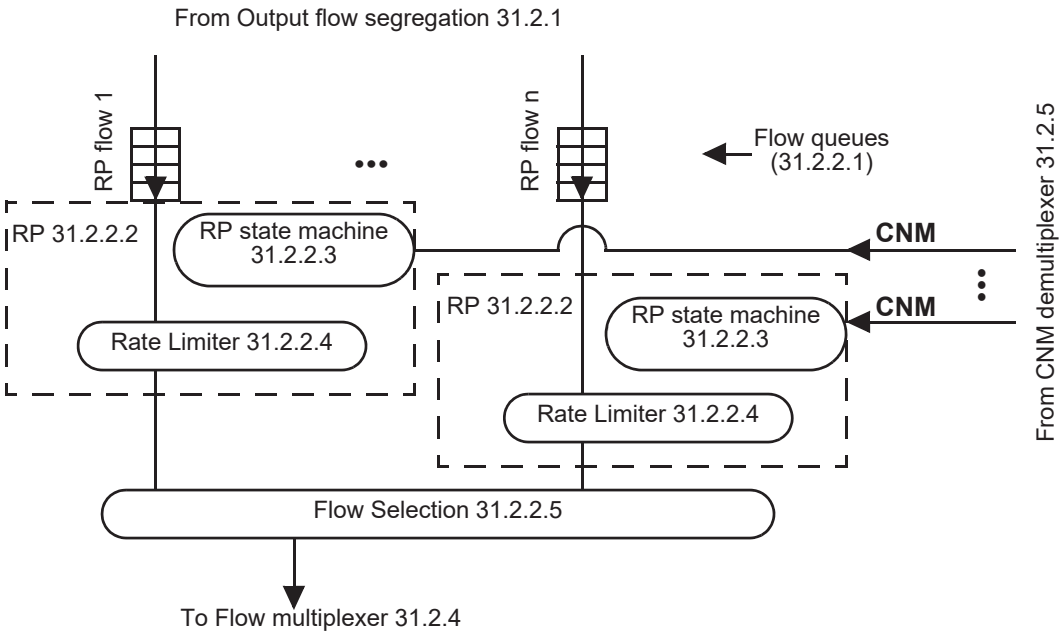

Figure 31-3—Per-CNPV station function

31.2.2.2 Reaction Point (RP)

A single RP is associated with each Flow queue. An RP is composed of a RP state machine (31.2.2.3) and a Rate Limiter (31.2.2.4).

31.2.2.3 RP state machine

A single RP state machine is associated with each Flow queue. As described in detail in Clause 32, the RP state machine consists of a timer (32.12), variables (32.10, 32.11, and 32.13), procedures (32.14), and a state machine (32.15) that determine the value of the rpLimiterRate variable (32.13.8), which, via the Rate Limiter (31.2.2.4), controls the transmission of frames from the Flow queue. The state machine and variables, in turn, are controlled by the frames input, managed objects (12.20.4), the Output flow segregation entity (31.2.1), and the CNMs received from the CNM demultiplexer (31.2.5).

31.2.2.4 Rate Limiter

A single Rate Limiter is associated with each Flow queue. The Rate Limiter enforces the output rate, rpLimiterRate (32.13.8), determined by the RP state machine (31.2.2.3). The octets in the frames passed from the Rate Limiter to the Flow Selection function (31.2.2.5) are counted in rpByteCount (32.13.2). The details of the operation of the Rate Limiter are not specified by this standard, but the measurable output rate is specified.

For a given measurement period T, R_T is defined as the integral of rpLimiterRate over T, and L_T as the number of octets actually output to the LAN, including preambles, inter-frame gaps, etc., stemming from frames that pass through that RP's Rate Limiter. An end station shall ensure that:

$$L_T \leq (1.05 \times R_T) + (16 \text{ maximum-sized frames}) \quad (31\text{-}1)$$

for the two values of T = one second and T = 1 million bits divided by the physical line rate (in bits per second), where any number of simultaneous measurements can start at any time.

NOTE 1—The rate computations and variables [Equation (31-1), 32.13.6, 32.11.6, etc.] include all of the octets associated with a frame on the LAN, including preambles, inter-frame gaps, etc., and thus reflect actual physical data rates. However, the resource actually protected by congestion notification is octets in buffers, not octet times on wires. Per-frame overhead on the LAN is added to serve as a reasonable approximation, made at the RP, to the actual size of the frame in the Bridges' or end stations' buffers. The extra 5% margin in Equation (31-1) is provided because this approximation is inexact.

NOTE 2—Although the simulations have been studied with a burst of one maximum-sized frame, this standard allows the end stations to send data in bursts of 16 maximum-sized frames, primarily to ease implementations. Larger bursts of data have a negative impact on the overall performance of the QCN algorithm, and can lead to lower link utilization.

31.2.2.5 Flow Selection

The Flow Selection function decides from which Flow queue in its Per-CNPV station function, if any, a frame will be offered to the Flow multiplexer. Whenever the output queue that receives frames from the Flow Selection function (via the Flow multiplexer) is full, the Flow Selection function shall not present any frame to the Flow multiplexer; this ensures that no frames in CNPVs will be discarded in the Port due to a lack of room in the output queue.

By means unspecified in this standard, the Flow Selection function selects frames to pass to the Flow multiplexer from the uncontrolled Flow queues (31.2.2.1) and Rate Limiters (31.2.2.4). Whenever a frame is passed from a Rate Limiter through the Flow Selection function to the Flow multiplexer, the Flow Selection function calls TransmitDataFrame (32.14.3) to update the RP variables (32.13). If the port's neighbor is ready to receive frames with CN-TAGs for the frame's CND (defense mode is cptInteriorReady), the Flow Selection function may insert a CN-TAG (30.5) at the beginning of the frame's mac_service_data_unit, and if not (any CND defense mode other than cptInteriorReady), it shall not insert a CN-TAG. (See 33.2 for a further explanation of CN-TAG insertion.)

31.2.3 Flow Select Database

The Flow Select Database is used by the Output flow segregation (31.2.1) entity to determine to which Flow queue (31.2.2.1) a given frame is assigned.

The means by which the Flow Select Database selects a Flow queue is unspecified by this standard.

31.2.4 Flow multiplexer

The Flow multiplexer merges the frames from the Per-CNPV station functions' Flow Selection functions (31.2.2.5), the frames bypassing the Per-CNPV station functions, and the CNM frames from the CPs (31.1.1), and delivers the frames to the Queuing frames (8.6.6) entity in the end station's output path.

31.2.5 CNM demultiplexer

The CNM demultiplexer identifies CNMs received from the LAN, uses the Flow ID (33.2.1) and/or Encapsulated priority (33.4.7) to determine to which RP (31.2.2.2) each CNM is intended, and directs them to the correct RPs. This standard does not specify whether or how the end station can use the Flow ID to further identify one or more individual flows within a Flow queue and its associated RP. If a CNM is received that has no CN-TAG, or a CN-TAG whose Flow ID is unknown to the RP, the CNM is discarded. All non-CNM frames are passed to the Input flow segregation entity (31.2.6).

31.2.6 Input flow segregation

For each frame received from the lower layers for reception, the Input flow segregation entity:

a) If the frame's priority is not a CNPV, decides, in an unspecified manner, whether to pass the frame to an unspecified queue, pass it to the higher layers, or discard it.
b) If the frame's priority is a CNPV, passes the frame to a CP (31.1.1), selected by unspecified means, for processing.

NOTE 1—For example, an end station might support a single CP, or support one CP per CNPV, per VID, per application, or per data flow. Neither these nor any choices for CP selection are required by this standard.

The Input flow segregation entity never discards a CNPV frame. Every CNPV frame presented to it is passed to a CP, as described previously.

NOTE 2—This does not mean that a station cannot drop CNPV frames. See 31.2.7.

31.2.7 End station input queue

The number and operation of end station input queues and the method used to drain these queues (i.e., to select and transfer frames to the receiving higher layer applications) are not specified by this standard. However, the procedures performed by a CP (32.9) require that its associated end station input queue exist, and possess certain operational parameters (32.8).

In the unfortunate event that a misconfiguration or an unfortunate sequence of frame transmissions results in more CNM frames arriving at a station than it can process, an end station input queue can fill up, and discard a frame presented to it by its CP or by the Input flow segregation (31.2.6) entity.

31.2.8 Reception selection

The Reception selection entity selects frames for delivery to the upper layers. It takes the place of the Transmission selection entity (8.6.8) of a congestion-aware Bridge. The selection algorithm depends on interactions between the applications receiving the data, the operating system supporting those applications, and the received frames that are not specified by this standard. The Reception selection entity is shown in Figure 31-2 for completeness, to indicate that frames enqueued by the Queuing frames entity (8.6.6) are, in fact, removed from the queues.

If the first octets of the mac_service_data_unit of a frame selected by the Reception selection entity are a CN-TAG, Reception selection removes the CN-TAG from the mac_service_data_unit before passing the frame to the higher layers. (See 33.2 for a further explanation of CN-TAG removal.)

32. Congestion notification protocol

Congestion-aware systems can participate in the congestion notification protocols specified in this clause:

a) CND operations (32.1).
b) The variables controlling congestion notification at the end station or Bridge component (32.2) and Port and CNPV levels (32.3).
c) The variables (32.4), procedures (32.5), and state machine (32.6) that control the defense of a CND.
d) The congestion notification protocol (32.7).
e) The variables (32.8) and procedures (32.9) that define a CP.
f) The variables associated with all (32.10), or a subset of (32.11), the RPs on a given Port and CNPV.
g) The timer (32.12), variables (32.13), procedures (32.14), and state machine (32.15) that define the operation of a single a RP.
h) The processing of CNMs by a congestion notification and encapsulation interworking function (32.16).

NOTE—Clause 30 introduces the principles of congestion notification operation and the network architectural concepts that support it. Clause 31 breaks down the congestion notification entities into their components. Clause 33 specifies the encoding of the PDUs used by congestion notification.

32.1 CND operations

As described in 30.6, a CND is a connected subset of a Virtual Bridged Network configured to support a particular CNPV. This standard provides a means whereby a VLAN Bridge or end station can recognize the like-configured ports of a CND (32.1.1), and defend its CND against incoming frames from outside the CND.

32.1.1 CND defense

Unless every Bridge along a path between two congestion-aware end stations using a particular CNPV is configured for congestion notification (belongs to a CND), and unless the Bridges ensure that frames not in CNPVs use different queues than the queues used by those two end stations, those end stations will not accrue the advantages that congestion notification offers. Therefore, steps must be taken at the boundaries of a CND to protect both the CND and the network outside the CND.

Every frame received on a Port passes through the ISS Support by specific MAC procedures (IEEE Std 802.1AC), which can change the priority parameter of the received frame, using the Port's Priority regeneration table, Table 6-4. This table can be controlled by a managed object (12.6). In addition, in order to prevent frames not in CNPVs from entering CP-controlled queues, each Port's Priority regeneration table can be modified.

If a Port's neighbor is known to also be configured for a particular CNPV, the entry in the Port's Priority regeneration table for that CNPV is ignored, and the priority is never changed on input. The Bridge component or end station connected to that Port can be trusted to use that CNPV. If the Port's neighbor is known to not be configured for a particular CNPV, the entry in the Port's Priority regeneration table for that CNPV shall be overridden to translate the CNPV to an alternate non-CNPV value. The neighboring system is not trusted, so the priority values of any frames carrying the CNPV's value are changed. Altering the priority values of received frames defends the CND from frames not originating from an RP. Similarly, if a CNPV is configured on any Port, then on that Port, the Port's Priority regeneration table shall be overridden to prevent any other priority value from being remapped into that CNPV.

If a port has multiple neighbors, or if the neighbor on a Port is not congestion aware, then the CN-TAGs shall be removed from any frames transmitted on a CNPV. This ensures that the benefits of congestion notification can be provided as far as possible along a path from a congestion-aware source to a

noncongestion-aware destination. Furthermore, CN-TAGs shall be removed from any frames transmitted from a CNPV toward a system that is congestion aware, but is still remapping the CNPV to a non-CNPV priority.

Thus, for each priority value, the CND defense mode can take one of the following four values, whether derived from LLDP or set by managed variables:

— **cptDisabled:** The congestion notification capability is administratively disabled for this priority value and port. This priority is not a CNPV. The priority regeneration table (6.9.4) controls the remapping of input frames on this port to or from this priority. CN-TAGs are neither added by an end station nor stripped by a Bridge.

— **cptEdge:** On this port and for this CNPV, the priority parameters of input frames are remapped to an alternate (non-CNPV) value, and no priority value is remapped to this CNPV, regardless of the priority regeneration table. CN-TAGs are not added by an end station and are removed from frames before being output by a Bridge.

NOTE—The cptEdge CND defense mode is optional for an end station. See 32.4.9.

— **cptInterior:** On this port and for this CNPV, the priority parameters of input frames are not remapped to another value, and no priority value is remapped to this CNPV, regardless of the priority regeneration table. CN-TAGs are not added by an end station, and are removed from frames before being output by a Bridge.

— **cptInteriorReady:** On this port and for this CNPV, the priority parameters of input frames are not remapped to another value, and no priority value is remapped to this CNPV, regardless of the priority regeneration table. CN-TAGs can be added by an end station and are not removed from frames by a Bridge.

The determination of the operational state of a CNPV on a given port is determined by variables and by LLDP (32.1.1, 32.2.1, 32.3.7, 32.3.4, 32.4.1, 32.4.3).

Taken together, these capabilities ensure that as long as the default values of the managed variables controlling CND defense are not overridden with incorrect values:

a) A data frame received by an end station on a CNPV has been governed by congestion notification along its entire path from the transmitting end station.
b) Uncontrolled data streams sourced by an end station that is congestion unaware cannot pass through a CP, with a resultant excessive loss of congestion-aware frames.
c) A data frame carrying a CN-TAG cannot be delivered to a system that is congestion unaware, and thus be unreadable by that system.

It is therefore recommended that the network administrator allow CND recognition to operate automatically (32.1.2).

CND defense operates on each LAN separately; it does not ensure the existence of an end-to-end congestion-aware path from end station to end station through a VLAN Bridged Network. Misconfiguration, the presence along the path of a congestion unaware Bridge, or the activation of a new Bridge or LAN (temporarily) can cause frames to exit a CND, and hence the following to occur:

d) Data frames can be transmitted by a congestion-aware end station on a CNPV, then be uncontrolled for congestion along some part of their path, and be delivered to an end station on a non-CNPV priority value with no CN-TAG.
e) If a congestion-aware end station transmits data frames with CN-TAGs, and is connected to a congestion unaware end station along a path consisting entirely of congestion unaware or misconfigured Bridges, the receiving end station will be unable to understand the CN-TAG, and thus unable to process the data frames.

f) If a system generates CNMs on a CNPV (not recommended, see 32.2.2), they can be delivered on a non-CNPV priority value with no CN-TAG.

32.1.2 Automatic CND recognition

Congestion notification can use the Link Layer Discovery Protocol (LLDP), defined in IEEE Std 802.1AB, to advertise the CNPVs supported on a Bridge's or end station's port, to determine whether the other Bridges' or end stations' ports connected to the same LAN are configured for those same CNPVs, and to control the operation of the CND defenses (32.1.1).

Multiple instances of LLDP can be run on a single port. Each instance's LLDPDUs use a different destination_address and therefore can reach different distances through a Virtual Bridged Network, depending on the types of the devices in that network and their connectivity. Since any Bridge that is not congestion aware can spoil the ability of the Virtual Bridged Network to minimize frame loss, the selection of which LLDP instance is used for CND defense defaults to the Nearest Bridge Address (01-80-C2-00-00-0E). This instance minimizes the reach of LLDP, and hence the risk that a noncongestion-aware Bridge is present.

As described in D.2.7, a single Congestion Notification TLV can be inserted into the LLDPDUs transmitted from any Bridge or end station port that is configured to support a CNPV. The Congestion Notification TLV carries two fields that together provide for automatic control the of the CND defenses:

a) Eight per-priority CNPV indicators (D.2.7.3), one per priority level, indicating whether each priority is or is not a CNPV on this port; and
b) Eight per-priority Ready indicators (D.2.7.4), one per priority level, indicating whether the priority remap defenses are disabled on this port.

For every CNPV configured on a port, if LLDP finds exactly one remote neighbor, and if that neighbor's database in the port's LLDP table carries a Congestion Notification TLV (D.2.7) with that CNPV's bit set in the per-priority CNPV indicators, then that CNPV is known to be configured on the remote system's port. This condition is summarized by the cnpdRcvdCnpv variable (32.4.11). Similarly, the cnpdRcvdReady variable (32.4.11) indicates whether the remote neighbor has or has not turned off its priority remapping defense. The read-only managed object cnpdAutoDefenseMode (32.4.3) indicates the results of the LLDP.

32.1.3 Variables controlling CND defense

In order to control CND defense, CN component managed objects (12.21.1), CN component priority managed objects (12.21.2), CN Port priority managed objects (12.21.3), and Congestion Point managed objects (12.21.4) override and are overridden by each other as follows:

a) Altering the CN component managed object (12.21.1) or CN component priority managed object (12.21.2) does not alter the values of any of the other managed objects (12.21.3, 12.21.4, 12.21.6).
b) If cngMasterEnable (32.2.1) is FALSE, all congestion notification activity is suppressed; the Priority Regeneration Table (6.9.4) operates normally, and CNMs, CN-TAGs, and LLDP Congestion Notification TLVs are never generated and are always ignored on receipt. If TRUE, the other managed objects control the operation of congestion notification.
c) The Port/priority and component objects override each other as shown in Table 32-1 and Table 32-2. In each case, if the Port/priority object contains the specified value, the component or component/priority object controls the specified function.

Table 32-1—LLDP instance selection managed object overrides

(Per-port per-priority) cnpdLldpInstanceChoice 32.4.4	(Component per-priority) cncpLldpInstanceChoice 32.3.6	Congestion Notification TLV is sent/received	LLDP instance is selected by
cnlNone	any	No	None selected
cnlAdmin	any	Yes	(Per-port per-priority) cnpdLldpInstanceSelector 32.4.5
cnlComponent	cnlNone	No	None selected
cnlComponent	cnlAdmin	Yes	(Component per-priority) cncpLldpInstanceSelector 32.3.7

Table 32-2—CND defense mode selection managed object overrides

(Per-port per-priority) cnpdDefModeChoice 32.4.1	(Component per-priority) cncpDefModeChoice 32.3.1	CND defense mode is selected by	Alternate priority is selected by
cpcAdmin	any	(Per-port per-priority) cnpdAdminDefenseMode 32.4.2	(Per-port per-priority) cnpdAlternatePriority 32.4.6
cpcAuto	any	(Per-port per-priority) cnpdAutoDefenseMode 32.4.3	(Component per-priority) cncpAutoAltPri 32.3.3
cpcComp	cpcAdmin	(Component per-priority) cncpAdminDefenseMode 32.3.4	(Component per-priority) cncpAlternatePriority 32.3.2
cpcComp	cpcAuto	(Per-port per-priority) cnpdAutoDefenseMode 32.4.3	(Component per-priority) cncpAutoAltPri 32.3.3

32.2 CN component variables

Every congestion-aware end station or Bridge component has a set of CN component variables to control the overall operation of congestion notification. All of these variables are included in the CN component managed object (12.21.1). Variables marked, “CP only” are not required for an end station that does not support CPs. The CN component variables include the following:

a) cngMasterEnable (32.2.1)
b) cngCnmTransmitPriority (32.2.2)
c) cngDiscardedFrames (32.2.3)
d) cngErroredPortList (32.2.4)

32.2.1 cngMasterEnable

A Boolean value specifying whether congestion notification is enabled in this Bridge component or end station.

32.2.2 cngCnmTransmitPriority

(CP only) The priority value to be used when transmitting CNMs from this Bridge component or end station (default 6) [item h) in 32.9.4].

NOTE—If cngCnmTransmitPriority is itself a CNPV, then it is possible that another CP could generate a CNM in response to a CNM sent by this Port. Although this is not desirable, the fact that CNMs are sent in response to only a sampling of frames means that the network will not fail due to an excessive number of CNMs.

32.2.3 cngDiscardedFrames

(CP only) The total number of frames discarded from full CP queues. This is the total of the values of all cpDiscardedFrames (32.8.12) variables for this end station or Bridge component.

32.2.4 cngErroredPortList

(CP only) A list of Ports whose alternate priority values (cnpdAlternatePriority, 32.4.6) specify a CNPV, where 0 indicates that the Bridge's alternate priority value (cncpAlternatePriority, 32.3.2) specifies a CNPV.

NOTE—The alternate priority (cncpAlternatePriority, 32.3.2, or cnpdAlternatePriority, 32.4.6) for a given CNPV cannot itself be a CNPV. But, because alternate priority values can be set using different managed objects for different CNPVs, invalid configurations can be specified. cngErroredPortList provides the network administrator with a list of Ports that could have invalid configurations.

32.3 Congestion notification per-CNPV variables

An instance of the congestion notification per-CNPV variables exists for each CNPV in a congestion-aware end station or Bridge component to control CN for all Ports in the end station or Bridge component. Variables marked "CP only" are not required for an end station that does not support CPs. The congestion notification per-CNPV variables include the following:

a) cncpDefModeChoice (32.3.1)
b) cncpAlternatePriority (32.3.2)
c) cncpAutoAltPri (32.3.3)
d) cncpAdminDefenseMode (32.3.4)
e) cncpCreation (32.3.5)
f) cncpLldpInstanceChoice (32.3.6)
g) cncpLldpInstanceSelector (32.3.7)

32.3.1 cncpDefModeChoice

An enumerated value specifying how the CND defense mode and alternate priority for all Ports for this CNPV are to be selected, unless overridden (32.1.3) by the variables in the CND defense per-Port per-CNPV variables (32.4), either one of the following:

1) **cpcAdmin:** The Port's default CND defense mode for this priority is controlled by cncpAdminDefenseMode (32.3.4) and the alternate priority by cncpAlternatePriority (32.3.2); or
2) **cpcAuto:** The Port's default CND defense mode for this priority is controlled by LLDP and the Congestion Notification TLV (cnpdAutoDefenseMode, 32.4.3) and the alternate priority by cncpAutoAltPri (32.3.3).

32.3.2 cncpAlternatePriority

(CP only) An alternate priority value to which this priority value is to be remapped when the Port's CND defense mode is cptEdge for this priority (default value 0). This can be overridden by cnpdAlternatePriority (32.1.3, 32.4.6).

32.3.3 cncpAutoAltPri

An integer indicating the next lower priority value than this CNPV that is not a CNPV in an end station or Bridge component, or the next higher non-CNPV, if all lower values are CNPVs (32.1.1).

32.3.4 cncpAdminDefenseMode

An enumerated value controlling the CND defense mode (30.6) for all Ports for this CNPV in this Bridge component or end station: cptDisabled (1), cptInterior (2, the default value), cptInteriorReady (3), or cptEdge (4) (32.1.1). This can be overridden by cnpdAdminDefenseMode (32.1.3, 32.4.2).

32.3.5 cncpCreation

An enumerated value controlling the applicability of this CN component priority managed object to the Ports in that Bridge component or end station, either one of the following:

1) **cncpAutoEnable:** The cnpdDefModeChoice variable (32.4.1) in any CN Port priority managed object created as a result of the creation of this CN component priority managed object or the creation of a Port is given the value cpcComp (3); or
2) **cncpAutoDisable:** The cnpdDefModeChoice variable (32.4.1) in any CN Port priority managed object created as a result of the creation of this CN component priority managed object or the creation of a Port is given the value cpcAdmin (1).

32.3.6 cncpLldpInstanceChoice

Determines the method by which the component LLDP instance selector, specifying on which LLDP instance the Congestion Notification TLV is to carry information for this priority, is determined (32.1.1), either one of the following:

1) **cnlNone:** if LLDP is not to carry Congestion Notification TLVs on any Port or priority; or
2) **cnlAdmin:** If cncpLldpInstanceSelector (32.3.7) governs LLDP instance selection for all Ports and priorities (this is the default value).

This choice can be overridden (32.1.3) on a per-Port per-priority basis by cnpdLldpInstanceChoice (32.4.4).

32.3.7 cncpLldpInstanceSelector

A reference to the LLDP destination address table entry whose LLDPDUs are to carry Congestion Notification TLVs for this Bridge component or end station (32.1.1). The use of this variable is controlled by cncpLldpInstanceChoice (32.3.6).

32.4 CND defense per-Port per-CNPV variables

For each Port in a congestion-aware end station or Bridge component, and for each priority value for which a set of congestion notification per-CNPV variables exists, there is an instance of the CND defense per-Port per-CNPV variables. These variables control congestion notification on the port for a CNPV, including CND defense. Variables marked, “CP only” are not required for an end station that does not support CPs. The CND defense per-Port per-CNPV variables include the following:

a) cnpdDefModeChoice (32.4.1)
b) cnpdAdminDefenseMode (32.4.2)
c) cnpdAdminDefenseMode (32.4.2)
d) cnpdAutoDefenseMode (32.4.3)
e) cnpdLldpInstanceChoice (32.4.4)
f) cnpdLldpInstanceSelector (32.4.5)
g) cnpdAlternatePriority (32.4.6)
h) cnpdXmitCnpvCapable (32.4.7)
i) cnpdXmitReady (32.4.8)
j) cncpDoesEdge (32.4.9)
k) cnpdAcceptsCnTag (32.4.10)
l) cnpdRcvdCnpv (32.4.11)
m) cnpdRcvdReady (32.4.12)
n) cnpdIsAdminDefMode (32.4.13)
o) cnpdDefenseMode (32.4.14)

32.4.1 cnpdDefModeChoice

An enumerated value specifying how the CND defense mode and the alternate priority of the Port for this priority is to be determined, (30.6, 32.1.1, 32.1.1):

1) **cpcAdmin:** The Port’s CND defense mode for this priority is controlled by cnpdAdminDefenseMode (32.4.2), and the alternate priority by cnpdAlternatePriority (32.4.6);
2) **cpcAuto:** The Port’s CND defense mode for this priority is controlled by LLDP and the Congestion Notification TLV (cnpdAutoDefenseMode, 32.4.3) and the alternate priority by cncpAutoAltPri (32.3.3); or
3) **cpcComp:** The Port’s CND defense mode for this priority is controlled by cncpDefModeChoice (32.3.1) and the alternate priority by cncpAutoAltPri (32.3.3) (this is the default value).

32.4.2 cnpdAdminDefenseMode

An enumerated value specifying the CND defense mode of the Port for this priority, if and only if cnpdDefModeChoice (32.4.1) has the value cpcAdmin (1) (30.6, 32.1.1, 32.1.1):

1) **cptDisabled:** The CP is disabled on this port for this CNPV. Priority regeneration on input is controlled by the priority regeneration table. This is the same behavior as when cngMasterEnable (32.2.1) has the value FALSE. (This is the default value.);
2) **cptInterior:** The priority parameter of frames input are not remapped to or from this priority, and CN-TAGs are not output;
3) **cptInteriorReady:** The priority parameter of frames input are not remapped to or from this priority, and CN-TAGs can be output; or
4) **cptEdge:** The priority parameter of frames input at this priority are remapped to an alternate value, frames at other priorities are not remapped to this priority, and CN-TAGs are not output.

32.4.3 cnpdAutoDefenseMode

An enumerated value indicating the operating mode: cptInterior (2), cptInteriorReady (3), or cptEdge (4), in which the Port would operate for this CNPV if cnpdDefModeChoice (32.4.1) had the value cpcAuto (2).

NOTE—cncpAdminDefenseMode (32.3.4) is controlled by the network administrator. The object cnpdAutoDefenseMode (32.4.3) indicates what the CND defense mode would be, if it were controlled by the LLDP Congestion Notification TLV.

32.4.4 cnpdLldpInstanceChoice

Port and priority LLDP instance selector, specifying on which LLDP instance the Congestion Notification TLV is to carry information for this priority on this Port (32.1.1):

1) **cnlNone:** No LLDP Congestion Notification TLV is to carry Per-priority CNPV indicators or Per-priority Ready indicators on this Port for this priority;
2) **cnlAdmin:** cnpdLldpInstanceSelector (32.4.5) governs which LLDP instance is to carry Per-priority CNPV indicators and Per-priority Ready indicators for this priority in its Congestion Notification TLV on this Port; or
3) **cnlComponent:** cncpLldpInstanceSelector (32.3.7) governs LLDP instance selection for this Port and priority (this is the default value).

32.4.5 cnpdLldpInstanceSelector

A reference to the LLDP destination address table entry for an LLDP instance selector, specifying on which LLDP instance the Congestion Notification TLV is to carry information for this priority on this Port, if and only if cnpdLldpInstanceChoice (32.4.4) is set to cnlAdmin (2). Default value is 1. (32.1.1);

32.4.6 cnpdAlternatePriority

(CP only) An alternate priority value to which this priority value is to be remapped when the Port's CND defense mode is cptEdge for this priority, if and only if cnpdDefModeChoice (32.4.1) is set to cpcAdmin (1) (default value 0).

32.4.7 cnpdXmitCnpvCapable

Per-port per-priority Boolean variable indicating whether a given priority on this Port is (TRUE) or is not (FALSE) currently operating as a CNPV. cnpdXmitCnpvCapable is transmitted in the per-priority CNPV indicators in the Congestion Notification TLV (D.2.7.3). The variable is TRUE if and only if all of the following conditions are met:

a) cngMasterEnable (32.2.1) is TRUE; and
b) The CND defense mode, as selected by cncpDefModeChoice, cncpAdminDefenseMode, cnpdDefModeChoice, and cnpdAdminDefenseMode, according to Table 32-2, is not cptDisabled.

32.4.8 cnpdXmitReady

Per-port per-priority Boolean variable indicating whether the priority remap defenses for this port and CNPV have been disabled. cnpdXmitReady is transmitted in the per-priority Ready indicators in the Congestion Notification TLV (D.2.7.4). This variable is set and reset by the CND defense state machine (32.6).

32.4.9 cncpDoesEdge

Boolean variable indicating whether the cptEdge CND defense mode (32.1.1) is (TRUE) or is not (FALSE) implemented on this port for this priority. This variable is TRUE in a Bridge. In an end station, it may be either TRUE or FALSE. This variable is not a managed object.

NOTE—This variable, when FALSE, causes the state machine in Figure 32-1 to pass through the CNDD_EDGE state directly to the CNDD_INTERIOR state. Since the state machine takes, in theory, no time to execute, it is impossible to tell from any measurement taken outside the system whether the actions specified in the CNDD_EDGE state are actually executed.

32.4.10 cnpdAcceptsCnTag

Boolean variable indicating whether the CN-TAG is (TRUE) or is not (FALSE) acceptable on data frames received on this port for this CNPV. This variable is TRUE in a Bridge. In an end station, it may be either TRUE or FALSE. This variable is not a managed object.

NOTE—This variable can be used by an end station that finds it convenient for the adjacent Bridge to remove CN-TAGs from frames on a CNPV. By preventing this Port and CNPV's cnpdXmitReady variable from being set TRUE, (see Figure 32-1) cnpdAcceptsCnTag prevents the adjacent device's CND defense state machine (32.6) from advancing from the CNDD_INTERIOR state to the CNDD_INTERIOR_READY state, and thus prevents it from transmitting a CN-TAG on this CNPV.

32.4.11 cnpdRcvdCnpv

Per-port per-priority Boolean variable indicating the presence of an LLDP neighbor's Congestion Notification TLV (D.2.7). cnpdRcvdCnpv is TRUE only if all of the following are true:

a) An LLDP instance is selected by cncpLldpInstanceSelector (32.3.7) and cnpdLldpInstanceSelector (32.4.5);
b) The selected LLDP instance indicates that the Port has a single neighbor;
c) The selected LLDP instance's neighbor information includes a Congestion Notification TLV; and
d) That Congestion Notification TLV's Per-priority CNPV indicators field has a value of 1 in the position corresponding to this CNPV.

32.4.12 cnpdRcvdReady

Per-port per-priority Boolean variable indicating that the neighboring system has turned off its CND defenses. cnpdRcvdReady is TRUE only if all of the following are true:

a) cnpdRcvdCnpv is TRUE; and
b) The bit in the same Congestion Notification TLV's (D.2.7) Per-priority Ready indicators field (D.2.7.4) has a value of 1 in the position corresponding to this CNPV.

32.4.13 cnpdIsAdminDefMode

Boolean variable derived from the managed objects, indicating to the CND defense state machine (32.6) whether the CND defense mode is being forced to a particular state by the managed objects, as shown in Table 32-3.

NOTE—The purpose of this variable is to simplify the Boolean expressions in Figure 32-1.

32.4.14 cnpdDefenseMode

Enumerated value, indicating the management choice for the CND defense mode, if any, as shown in Table 32-3. The value of this variable is not defined if the managed variables indicate no choice for the CND defense mode.

Table 32-3—Determining cnpdIsAdminDefMode and cnpdDefenseMode

(Per-port per-priority) cnpdDefModeChoice (32.4.1)	(Component per-priority) cncpDefModeChoice (Clause 32)	cnpdIsAdminDefMode (32.4.13) is	cnpdDefenseMode (32.4.14) is obtained from
cpcAdmin	Any	TRUE	(Per-port per-priority) cnpdAdminDefenseMode 32.4.2
cpcAuto	Any	FALSE	Not defined
cpcComp	cpcAdmin	TRUE	(Component per-priority) cncpAdminDefenseMode 32.3.4
cpcComp	cpcAuto	FALSE	Not defined

NOTE—The purpose of this variable is to simplify the exit condition expressions in Figure 32-1.

32.5 CND defense procedures

There are three procedures associated with the CND defense state machine. They are as follows:

a) DisableCnpvRemapping() (32.5.1)
b) TurnOnCnDefenses() (32.5.2)
c) TurnOffCnDefenses() (32.5.3)

32.5.1 DisableCnpvRemapping()

Removes any overrides by congestion notification of the Priority Regeneration Table (6.9.4).

32.5.2 TurnOnCnDefenses()

Overrides the Priority Regeneration Table (6.9.4) to use the alternate priority specified by cncpAlternatePriority (32.3.2), cncpAutoAltPri (32.3.3), and cnpdAlternatePriority (32.4.6) for frames with this CNPV, instead of the value in the Priority Regeneration Table.

32.5.3 TurnOffCnDefenses()

Overrides the Priority Regeneration Table (6.9.4) to not alter the priority of incoming frames with this CNPV, instead of using the value in the Priority Regeneration Table.

32.6 CND defense state machine

The CND defense state machine is illustrated in Figure 32-1. A congestion-aware Bridge component or end station shall implement one CND defense state machine per port per priority level.

NOTE—In Figure 32-1, global transitions are associated with each value of cnpdDefenseMode when the CND defense mode is chosen by the managed variables; the nonglobal transitions from state to state can take place only when the CND defense mode is chosen by LLDP.

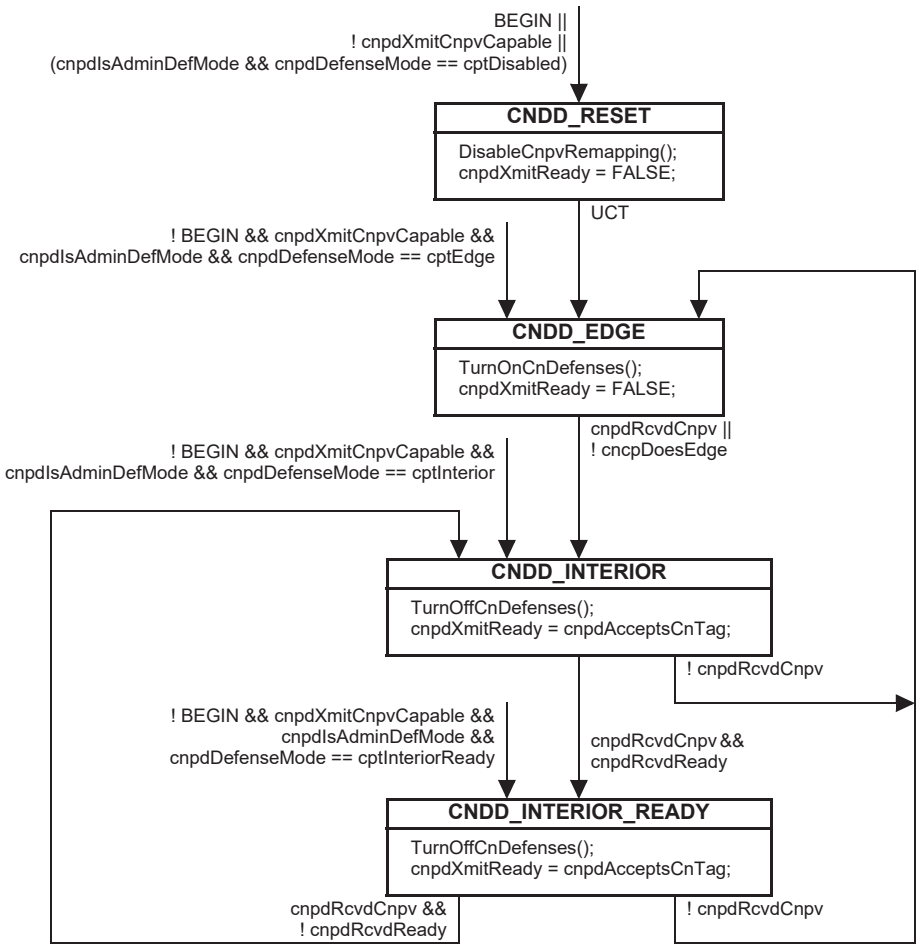

Figure 32-1—CND defense state machine

32.7 Congestion notification protocol

Clause 32 is a detailed specification of the state machines required to implement the QCN algorithm introduced in 30.2. Table 32-4 shows the correlation between the description of QCN in 30.2, the state machine variables in this clause, and the CNM PDU fields in 33.4.

There are two stateful participants in the congestion notification protocol:

a) The CP (31.1.1) shall behave in a manner that is indistinguishable, from an observer external to a system, from a strict implementation of the variables in 32.8 and the procedures in 32.9.
b) The RP (31.2.2.2) shall behave in a manner that is indistinguishable, from an observer external to a system, from a strict implementation of the timer in 32.12, variables in 32.13, the procedures in 32.14, and the state machine in 32.15.

Table 32-4—Correspondence of QCN and CCF message fields

Quantized Congestion Notification protocol, 30.2	Congestion notification protocol, 32.7	Congestion Notification Message, 33.3
Quantized Feedback calculation (32.8.9, item e) in 32.9.4)		
F_b (30.2.1)	—	cpFb (33.4.3)

32.8 CP variables

The following variables control the operation of a CP:

a) cpMacAddress (32.8.1)
b) cpId (32.8.2)
c) cpQSp (32.8.3)
d) cpQLen (32.8.4)
e) cpQLenOld (32.8.5)
f) cpW (32.8.6)
g) cpQOffset (32.8.7)
h) cpQDelta (32.8.8)
i) cpFb (32.8.9)
j) cpEnqued (32.8.10)
k) cpSampleBase (32.8.11)
l) cpDiscardedFrames (32.8.12)
m) cpTransmittedFrames (32.8.13)
n) cpTransmittedCnms (32.8.14)
o) cpMinHeaderOctets (32.8.15)

32.8.1 cpMacAddress

The MAC address, belonging to the system transmitting the CNM PDU, used as the source_address of CNMs sent from this CP [item b) in 32.9.4].

32.8.2 cpId

Unsigned integer. A number that uniquely identifies a CP in a Virtual Bridged Network [item p) in 32.9.4].

NOTE—This standard does not specify whether the Congestion Point Identifier (CPID) reported in a CNM by a CP that serves multiple CNPVs does or does not have the same value for its different CNPVs.

32.8.3 cpQSp

Unsigned integer. The set-point for the queue. This is the target number of octets in the CP's queue [item e) in 32.9.4]. Default value 26000.

32.8.4 cpQLen

Unsigned integer. The current number of octets in the CP's queue [item c) in 32.9.4].

32.8.5 cpQLenOld

Unsigned integer. The previous value of cpQLen. cpQLenOld is updated from cpQLen each time GenerateCnmPdu() is called [item c) in 32.9.4].

32.8.6 cpW

Real number. cpW is the weight to be given to the change in queue length in the calculation of cpFb (32.8.9). Default value 2. Although cpW is specified as a real number, it is constrained to be a power of 2, e.g., 1/2, 1, 2, 4. In practice, therefore, it can be represented as a shift distance (plus an addition) in item e) in 32.9.4.

32.8.7 cpQOffset

The signed integer value of the transmitting CP's cpQSp (32.8.3) – cpQLen (32.8.4) used to calculate cpFb (32.8.9), and thus the Quantized Feedback field (33.4.3).

32.8.8 cpQDelta

The signed integer value of the transmitting CP's cpQLen (32.8.4) – cpQLenOld (32.8.5) used to calculate cpFb (32.8.9), and thus the Quantized Feedback field (33.4.3).

32.8.9 cpFb

Signed integer. Calculated just before the CP attempts to enqueue a frame:

$$cpFb = cpQOffset - cpW \times cpQDelta,$$

where

$$cpQDelta = cpQLen - cpQLenOld \quad cpQOffset = cpQSp - cpQLen$$

cpFb has two terms. The first term is the difference between the current and the desired queue lengths (cpQOffset, 32.8.7). The second is a weight factor cpW times the difference cpQDelta (32.8.8) between the current and the previous queue lengths. Thus, a multiple of the first derivative of the queue size is subtracted from the current nonoptimality of the queue, so that if the queue length is moving toward the set point cpQSp, cpFb will be closer to 0 than if the queue length is moving away from cpQSp.

32.8.10 cpEnqued

Signed integer. The number of octets remaining to be enqueued by the CP before a CNM PDU is to be generated (32.9.3).

32.8.11 cpSampleBase

Unsigned integer. The minimum number of octets to enqueue in the CP's queue between CNM PDU transmissions (32.9.3). Default value 150 000.

32.8.12 cpDiscardedFrames

The number of frames offered to this CP that were discarded because of a full output queue (31.1.1).

32.8.13 cpTransmittedFrames

The number of data frames enqueued for transmission on this CP's output queue (31.1.1).

32.8.14 cpTransmittedCnms

The number of CNMs transmitted by this CP [item s) in 32.9.4].

32.8.15 cpMinHeaderOctets

The minimum number of octets that the CP is to return in the Encapsulated MSDU field (33.4.10) of each CNM it generates [item k) in 32.9.4]. Default value 0.

32.9 CP procedures

The procedures used in a CP include the following:

a) Random() (32.9.1)
b) NewCpSampleBase() (32.9.2)
c) EM_UNITDATA.request (parameters) (32.9.3)
d) GenerateCnmPdu() (32.9.4)

A CP needs no state machine; the procedure EM_UNITDATA.request (parameters), called each time a frame is presented for queuing, triggers all of the CP's functions.

32.9.1 Random

The Random function takes two parameters, min and max, and returns a pseudo-random number in the range min ≤ number < max. This function shall be initialized so that it generates a different value each time the system is reset.

32.9.2 NewCpSampleBase()

Called by EM_UNITDATA.request (parameters) (32.9.3) when generating a new value for cpSampleBase (32.8.11) from the CNM PDU Quantized Feedback field (33.4.3) last generated by GenerateCnmPdu(). NewCpSampleBase() returns a real number according to Table 32-5.

NOTE—The values in Table 32-5 are chosen so that the value returned by NewCpSampleBase() can be an integer to be used in a division, rather than a real number to be used in a multiplication.

Table 32-5—NewCpSampleBase() return value as a function of cpFb

Quantized Feedback / 8	Value returned by NewCpSampleBase()
0	1
1	1/2
2	1/3
3	1/4
4	1/5
5	1/6
6	1/7
7	1/8

32.9.3 EM_UNITDATA.request (parameters)

A CP offers an instance of the EISS (6.8) to the Queuing frames function (8.6.6). When called upon to enqueue a frame, the CP:

a) Determines the number of octets of buffer space required to enqueue the frame, and subtracts that number from cpEnqued (32.8.10).
b) If cpEnqued ≤ 0, then:
   1) Calculates a new value for cpFb according to 32.8.9.
   2) Calls GenerateCnmPdu() to conditionally transmit a CNM PDU.
   3) Replaces cpEnqued with cpSampleBase × NewCpSampleBase() × Random(0.85, 1.15), and if the result is less than zero, resets cpEnqued to 0.

The accuracy of the sample jitter introduced by the function Random(0.85, 1.15) is not critical to the success of congestion notification. The amount of jitter introduced by this function should be no more than 0.75 ≤ jitter < 1.25 and no less than 0.875 ≤ jitter < 1.125.

32.9.4 GenerateCnmPdu()

Called by the CP to conditionally generate a CN-TAGged CNM PDU for output. GenerateCnmPdu()

a) Uses the source_address of the frame triggering the CNM PDU as the destination_address of the generated CNM PDU.
b) Uses cpMacAddress (32.8.1) as the source_address of the CNM PDU.
c) Replaces the value of cpQLenOld (32.8.5) with cpQLen (32.8.4).
d) If cpFb is greater than or equal to 0, or if the destination_address parameter of the CNM PDU is a Group, and not an Individual, address, does nothing; no further processing takes place, and no CNM PDU is transmitted.
e) Fills the Quantized Feedback field (33.4.3) of the CNM PDU as follows:

   if (cpFb < – cpQSp × (2 × cpW + 1))

   Quantized Feedback = 63

   else

   Quantized Feedback = – cpFb × 63 / (cpQSp × (2 × cpW + 1))
f) If the Quantized Feedback field equal to 0 does nothing; no further processing takes place, and no CNM PDU is transmitted.

g) If the first octets of the mac_service_data_unit of the frame triggering the CNM PDU are a CN-TAG, copies the Flow Identifier field (33.2.1) from that CN-TAG to the CN-TAG of the CNM, else fills the Flow Identifier field of the CNM's CN-TAG with 0.

h) Sets the priority parameter of the CNM PDU from cngCnmTransmitPriority (32.2.2).

NOTE 1—The default value for the priority of a CNM PDU is 6. CNM PDUs are not expected to be sent in high volumes, but undelivered CNM PDUs reduce the ability of congestion notification to prevent lost data frames. Priority 7 is typically reserved for control traffic that, if not delivered, can result in the loss of connectivity in the Bridged Network.

i) Sets the vlan_identifier of the CNM PDU from the vlan_identifier of the frame triggering the CNM PDU, if the dot1agCfmVlanTable is not implemented, else the Primary VID of that vlan_identifier.

j) Fills the Encapsulated destination MAC address field (33.4.8) of the CNM PDU with the destination_address parameter of the frame triggering the CNM PDU.

k) Fills the Encapsulated MSDU field (33.4.10) of the CNM PDU with the first octets of the remainder of the mac_service_data_unit following the CN-TAG, if present, of the frame triggering the CNM PDU. The minimum number of octets is the value of cpMinHeaderOctets (32.8.15), or the whole of the mac_service_data_unit following the CN-TAG, if it is shorter, and the maximum is 64.

l) Fills the Encapsulated MSDU length field (33.4.9) of the CNM PDU with the number of octets inserted into the Encapsulated MSDU field (33.4.10).

m) Inserts the encapsulation appropriate to the CP's port, as specified in 33.3, at the beginning of the mac_service_data_unit.

NOTE 2—This encapsulation is changed by the Bridge, if required, before the CNM PDU is output on a port that uses a different encapsulation from the CP's port.

n) Fills the Version field (33.4.1) of the CNM PDU with 0.

o) Fills the ReservedV field (33.4.2) of the CNM PDU with 0.

p) Fills the Congestion Point Identifier field (33.4.4) of the CNM PDU from the variable cpId (32.8.2).

q) Computes and fills the cnmQOffset and cnmQDelta fields (33.4.5, 33.4.6) from the variables cpQOffset and cpQDelta.

r) Fills the Encapsulated priority field (33.4.7) from the priority parameter of the frame triggering the CNM PDU.

s) Increments cpTransmittedCnms (32.8.14).

t) Passes the CN-TAG and CNM PDU as an EM_UNITDATA.indication to the higher layers (Figure 31-1), if the CP is in a Bridge, or to the Flow multiplexer (31.2.4), if the CP is in an end station (Figure 31-2).

32.10 RP per-Port per-CNPV variables

There is one set of these variables per Port per CNPV in a congestion-aware end station. A set of RP per-Port per-CNPV variables is created or deleted whenever a CN Port priority managed object is created or deleted. All of the RPs (if more than one) associated with a given Port and CNPV share a single set of the RP per-Port per-CNPV variables.

32.10.1 rpppMaxRps

An unsigned integer controlling the maximum number of RPs allowed for this CNPV on this Port (default 1). An end station shall not create more than rpppMaxRps on a given Port, but it can create fewer.

32.10.2 rpppCreatedRps

The number of times an RP's rpEnabled variable has been set TRUE at this priority level on this Port [item e) in 32.4.14].

32.10.3 rpppRpCentiseconds

An integer containing the number of RP-centiseconds accumulated by RPs at this priority level on this Port. This variable is incremented once per centisecond (10 ms) for each RP on this Port whose rpEnabled variable (32.13.1) is TRUE.

NOTE—Reading rpppRpCentiseconds and SysUpTime[46] at two different times allows a management entity to compute the average number of RPs present for a priority and Port by dividing the change in rpppRpCentiseconds by the change in SysUpTime (which is measured in centiseconds).

32.11 RP group variables

There is one set of RP group variables for each group of RPs belonging to a particular CNPV on a Port in a congestion-aware end station. It is an implementation choice whether each RP rate control state machine (32.15) has its own set of RP group variables or shares them with another RP rate control state machine on the same Port and the same CNPV. This standard does not specify how RPs are grouped together for management purposes, except that all of the RPs controlled by a single set of RP group variables shall serve a single CNPV. At the extremes, a single set of RP group variables could control all of the RPs serving the same CNPV, or each RP could be controlled by its own set of RP group variables. The RP group variables include the following:

a) rpgEnable (32.11.1)
b) rpgTimeReset (32.11.2)
c) rpgByteReset (32.11.3)
d) rpgThreshold (32.11.4)
e) rpgMaxRate (32.11.5)
f) rpgAiRate (32.11.6)
g) rpgHaiRate (32.11.7)
h) rpgGd (32.11.8)
i) rpgMinDecFac (32.11.9)
j) rpgMinRate (32.11.10)

32.11.1 rpgEnable

A Boolean value controlling the rpEnabled variables for all of the RP rate control state machines controlled by this Reaction Point group managed object. If rpgEnable is TRUE, the controlled rpEnabled variables are not held in the FALSE state, thus enabling the RPs to pay attention to received CNMs. If rpgEnable is FALSE, the controlled rpEnabled variables are held in the FALSE state, thus disabling the RPs.

32.11.2 rpgTimeReset

Unsigned integer. RpWhile (32.12.1) is reset to either rpgTimeReset or rpgTimeReset / 2 (with random jitter—see Figure 32-2 in 32.15, RPR_ACTIVE_TIME) each time it reaches 0, according to the state of the RP rate control state machine. Default value 15 ms.

32.11.3 rpgByteReset

Unsigned integer. rpByteCount (32.13.2) is reset to either rpgByteReset or rpgByteReset / 2 (with random jitter—see Figure 32-2 in 32.15, RPR_ACTIVE_BYTE) each time it reaches 0, according to the state of the RP rate control state machine. Default value 150 000 octets.

[46] From IETF RFC 3418.

32.11.4 rpgThreshold

Unsigned integer. Specifies the number of times rpByteStage or rpTimeStage can count before the RP rate control state machine advances states. Default value is 5.

32.11.5 rpgMaxRate

Unsigned integer. The maximum rate, in bits per second, at which an RP can transmit. Default value is the speed of the Port. A system shall support a nonzero minimum value for rpgMaxRate no larger than 5 Mb/s. This rate includes all bits consequent to transmitting the frame on the LAN, including preamble, inter-frame gap, etc. rpgMaxRate is configurable in multiples of 1 Mb/s.

32.11.6 rpgAiRate

Unsigned integer. The rate, in bits per second, used to increase rpTargetRate in the RPR_ACTIVE_INCREASE state in Figure 32-2 in 32.15. Default value 5 Mb/s. This rate includes all bits consequent to transmitting the frame on the LAN, including preamble, inter-frame gap, etc. rpgAiRate is configurable in multiples of 1 Mb/s.

32.11.7 rpgHaiRate

Unsigned integer. The rate, in bits per second, used to increase rpTargetRate in the RPR_HYPER_INCREASE state in Figure 32-2 in 32.15. Default value 50 Mb/s. This rate includes all bits consequent to transmitting the frame on the LAN, including preamble, inter-frame gap, etc. rpgHaiRate is configurable in multiples of 1 Mb/s.

32.11.8 rpgGd

Real number. Multiplied times the Quantized Feedback field (33.4.3) received in a CNM PDU to decrease rpTargetRate. Default value 1/128. rpgGd is configurable as a power of 2, e.g., 1/256, 1/128, 1/64.

32.11.9 rpgMinDecFac

Real number. The minimum factor by which the current RP transmit rate rpCurrentRate can be changed by reception of a CNM. Default value is 0.5.

32.11.10 rpgMinRate

Unsigned integer. The minimum value, in bits per second, for rpCurrentRate (32.13.6) Default value is 10 Mb/s. A system shall support a minimum value for rpgMinRate no larger than 10 Mb/s. This rate includes all bits consequent to transmitting the frame on the LAN, including preamble, inter-frame gap, etc. rpgMinDecFac is configurable in multiples of 1 Mb/s.

32.12 RP timer

An RP implements one timer as follows:

a) RpWhile (32.12.1).

32.12.1 RpWhile

Timer counter for controlling the RP rate control state machine (32.15). RpWhile operates normally when rpFreeze (32.13.7) is FALSE, and shall not be decremented when rpFreeze is TRUE.

32.13 RP variables

Each RP rate control state machine (32.15) has its own set of RP variables. The RP variables include the following:

a) rpEnabled (32.13.1)
b) rpByteCount (32.13.2)
c) rpByteStage (32.13.3)
d) rpTimeStage (32.13.4)
e) rpTargetRate (32.13.5)
f) rpCurrentRate (32.13.6)
g) rpFreeze (32.13.7)
h) rpLimiterRate (32.13.8)
i) rpFb (32.13.9)

32.13.1 rpEnabled

Boolean. Controls RP rate control state machine. If TRUE, state machine is running. If FALSE, state machine is held in the RPR_RESET state. Initialized to FALSE when an RP rate control state machine is created. Held in the FALSE state if rpgEnable (32.11.1) has the value FALSE.

32.13.2 rpByteCount

Unsigned integer. Counts octets passed from the Rate Limiter (31.2.2.4) to the Flow Selection function (31.2.2.5). The counting down of rpByteCount to or past 0 triggers a reevaluation of rpCurrentRate (32.13.6).

32.13.3 rpByteStage

Unsigned integer. Counts the number of times rpByteCount has counted down to or past 0 since the last CNM was received.

32.13.4 rpTimeStage

Unsigned integer. Counts the number of times RpWhile has counted down to 0 since the last CNM was received.

32.13.5 rpTargetRate

Unsigned integer. The target rate, in bits per second, toward which rpCurrentRate is heading. This rate includes all bits consequent to transmitting the frame on the LAN, including preamble, inter-frame gap, etc.

32.13.6 rpCurrentRate

Unsigned integer. The rate, in bits per second, at which the Rate Limiter (31.2.2.4) transmits data from its Flow queue when rpFreeze (32.13.7) is FALSE. (The actual output of the Rate Limiter is controlled by rpLimiterRate, 32.13.8.) This rate includes all bits consequent to transmitting the frame on the LAN, including preamble, inter-frame gap, etc.

32.13.7 rpFreeze

Boolean. When FALSE, the RP and Rate Limiter operate normally. When TRUE, rpLimiterRate is held to the value 0, to suppress the transmission of frames. rpFreeze is FALSE when there is room for frames from this RP in the output queue, and TRUE when not.

32.13.8 rpLimiterRate

Unsigned integer. The rate, in bits per second, at which the Rate Limiter (31.2.2.4) transmits data from its Flow queue. rpLimiterRate is equal to rpCurrentRate (32.13.6) as long as rpFreeze (32.13.7) is FALSE, and 0, when rpFreeze is TRUE. This rate includes all bits consequent to transmitting the frame on the LAN, including preamble, inter-frame gap, etc.

32.13.9 rpFb

Unsigned integer. The value last received in the Quantized Feedback field (33.4.3) of a CNM PDU or 0.

32.14 RP procedures

The following procedures are used by the RP rate control state machine and the Output flow segregation function (31.2.1):

a) ResetCnm (32.14.1)
b) TestRpTerminate (32.14.2)
c) TransmitDataFrame (32.14.3)
d) ReceiveCnm (32.14.4)
e) ProcessCnm (32.14.5)
f) AdjustRates (32.14.6)

32.14.1 ResetCnm

Called whenever the RP rate control state machine enters the RPR_RESET state (Figure 32-2 in 32.15) to set the following variables:

— rpCurrentRate = rpgMaxRate
— rpTargetRate = rpgMaxRate
— rpByteCount = rpgByteReset
— rpFb = 0

32.14.2 TestRpTerminate

Called by the Flow Selection function (31.2.2.5) each time a frame is passed from the Per-CNPV station function's Rate Limiter (31.2.2.4) to the Flow multiplexer (31.2.4). If:

a) rpCurrentRate equals rpgMaxRate
b) The Flow queue is empty
c) rpEnabled is TRUE

Then TestRpTerminate sets rpEnabled (32.13.1) to FALSE, which disables the RP until another CNM is received.

NOTE—Condition b) can be met when all frames limited by a given Rate Limiter have been processed. See 31.2.2.1.

32.14.3 TransmitDataFrame

TransmitDataFrame() is called each time a frame is passed from a Rate Limiter (31.2.2.4) to the Port's Flow multiplexer (31.2.4). TransmitDataFrame() subtracts the length of the transmitted frame from rpByteCount (32.13.2) and may insert a CN-TAG containing the Flow ID of the Flow queue at the beginning of the frame's mac_service_data_unit.

If an end station is VLAN-aware or priority-aware, and if a CN-TAG is added to a frame, the CN-TAG shall follow the VLAN or priority tag in the frame.

32.14.4 ReceiveCnm

Called whenever a CNM is received. ReceiveCnm() performs the following actions:

a) The CNM is validated according to 33.4.11 and is discarded if invalid.
b) If the CNM frame carries a CN-TAG (33.2), the Flow ID from that CN-TAG (33.2.1) is used to identify the particular RP rate control state machine to which this CNM applies.
c) If the receiving end station is unable to identify the particular RP rate control state machine to which this CNM applies, it discards the CNM, and no further processing takes place.
d) Sets the rpFb variable from the CNM's Quantized Feedback field (33.4.3).
e) If the selected RP rate control state machine's rpEnabled variable is FALSE and is not held FALSE because rpgEnable (32.11.1) has the value FALSE, and the CNM's cnmQOffset field (33.4.5) is positive, then rpEnabled is reset to TRUE, and the variable rpppCreatedRps (32.10.2) is incremented.

These actions activate the selected RP rate control state machine, if it was not active (rpEnabled == FALSE), and also cause the RP rate control state machine to process the received CNM.

32.14.5 ProcessCnm

Called whenever the RP rate control state machine enters the RPR_CNM_RECEIVED state (Figure 32-2 in 32.15) to perform the following actions:

```
if (rpByteStage ! = 0) {
      rpTargetRate = rpCurrentRate;
      rpByteCount = rpgByteReset;
}
rpByteStage = 0;
rpTimeStage = 0;
dec_factor = (1 – (rpgGd * rpFb));
if (dec_factor < rpgMinDecFac)
      dec_factor = rpgMinDecFac;
rpCurrentRate = rpCurrentRate * dec_factor;
if (rpCurrentRate < rpgMinRate)
      rpCurrentRate = rpgMinRate;
RpWhile = rpgTimeReset;
```

32.14.6 AdjustRates

AdjustRates is called whenever the RPR_ADJUST_RATES, RPR_ACTIVE_INCREASE, or RPR_HYPER_INCREASE states are entered. It takes one parameter, *increase*, that specifies how much to increase rpTargetRate, and performs the following actions:

```
if ((rpByteStage == 1) || (rpTimeStage == 1))   &&   (rpTargetRate > 10 * rpCurrentRate))
      rpTargetRate = rpTargetRate / 8;
else
      rpTargetRate = rpTargetRate + increase;
rpCurrentRate = (rpTargetRate + rpCurrentRate)/2;
if (rpCurrentRate > rpgMaxRate)
      rpCurrentRate = rpgMaxRate;
```

32.15 RP rate control state machine

The RP rate control state machine is illustrated in Figure 32-2. In this figure, the RPR_RESET state has no exit. The state machine is held in the RPR_RESET state as long as either the general system initialization variable “BEGIN” is TRUE or the rpEnabled variable, local to the particular instance of the RP rate control state machine, is FALSE. When “BEGIN” becomes FALSE and rpEnabled TRUE, the state machine remains in the RPR_RESET state until a CNM is received by ReceiveCnm (32.14.4) with a Quantized Feedback field (33.4.3) that is less than 0. ReceiveCnm places that field into rpFb (32.13.9), which condition forces the state machine into the RPR_CNM_RECEIVED state. When that state resets rpFb to 0, progress through the state machine continues either until another CNM is received and rpFb is set to a nonzero value, or until the state machine is deactivated by TestRpTerminate (32.14.2) setting rpEnabled to FALSE.

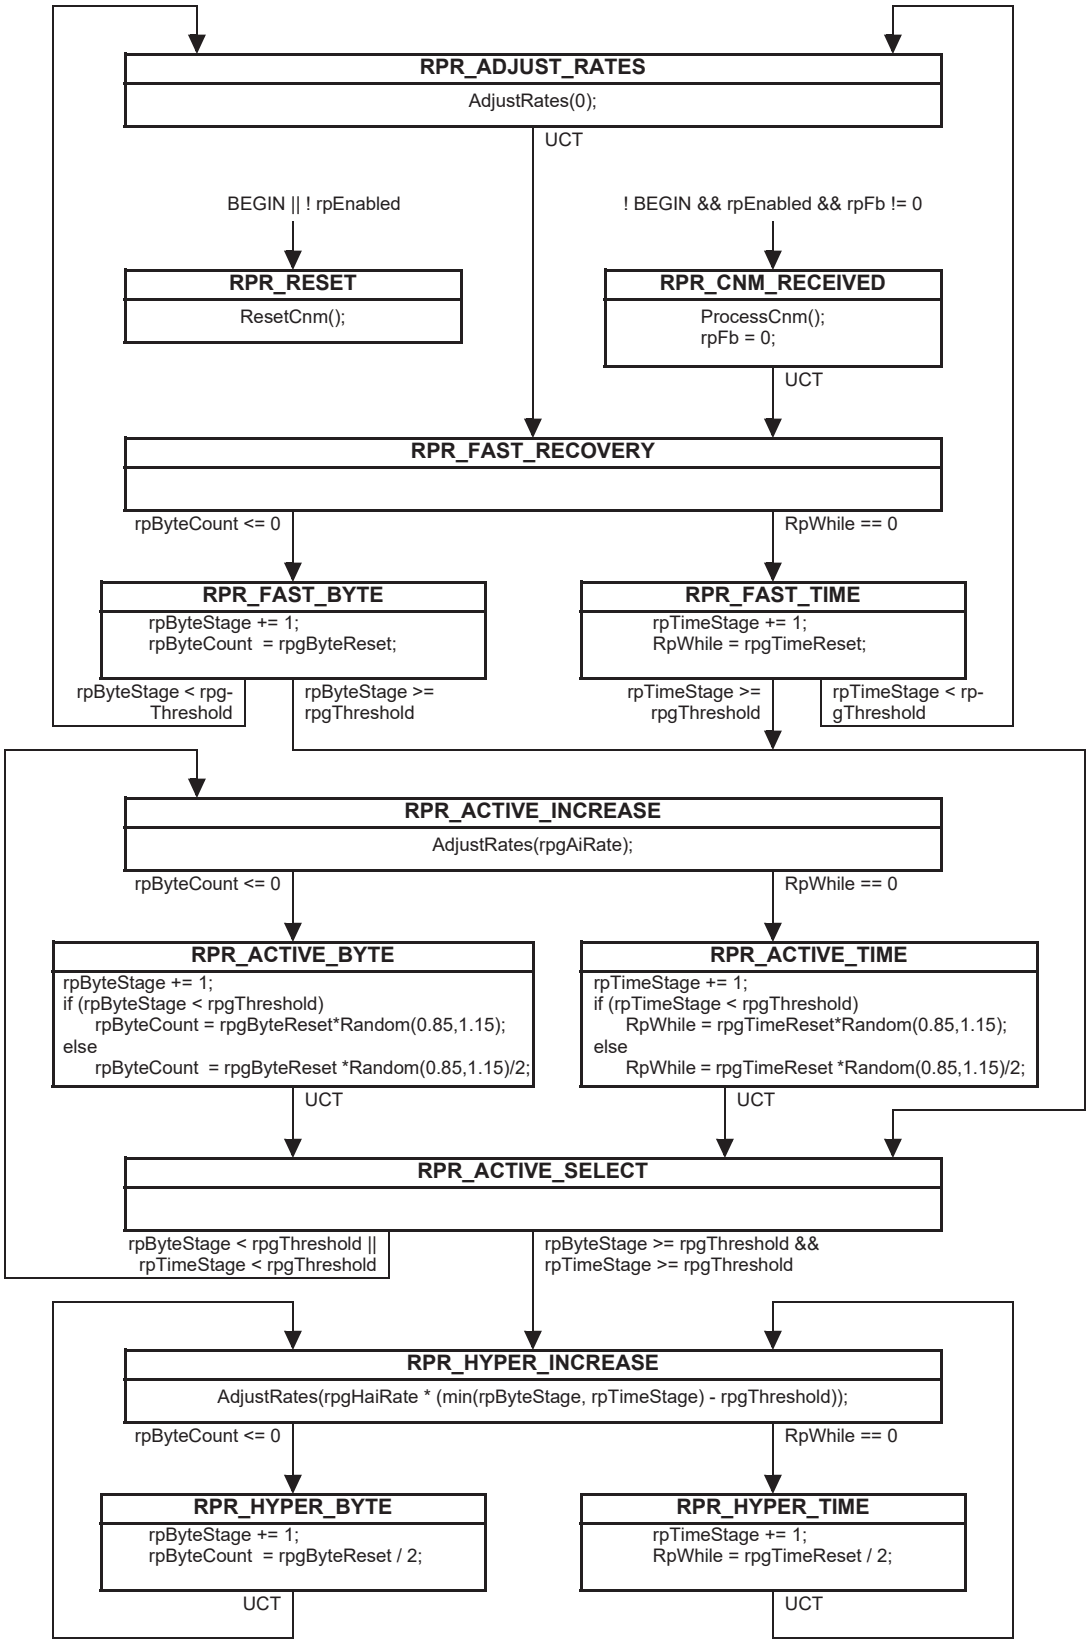

Figure 32-2—RP rate control state machine

32.16 Congestion notification and encapsulation interworking function

As mentioned in 30.8, a hierarchical Bridged Network, e.g., a PBBN, can require a congestion notification and encapsulation interworking function for a CP in the core of the network to generate a CNM that can reach the RP, which is presumably outside the core. This general case is illustrated in Figure 32-3. In the network illustrated, encapsulation and decapsulation functions peer with each other to encapsulate the data frames inside some kind of wrapper, e.g., an S-TAG and/or an I-TAG.

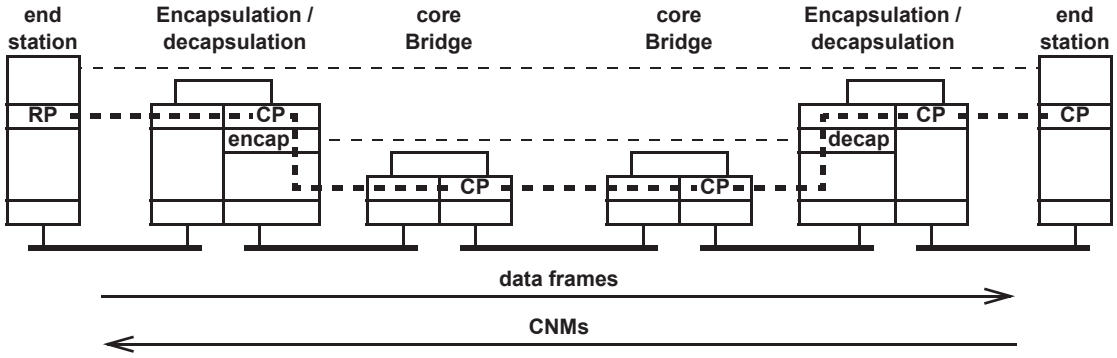

Figure 32-3—CP–RP peering in any hierarchical Bridged Network

Not all encapsulation schemes are equivalent. It is useful to divide hierarchical Bridged Networks into two categories for the purpose of defining congestion notification and encapsulation interworking functions, based on the mac_service_data_unit of a data frame carrying (optionally) a CN-TAG as seen by a CP residing in a core Bridge, with one of these cases further subdivided as follows:

a) In a network where the original end station's mac_service_data_unit, including the optional CN-TAG, comprises the first octets of the mac_service_data_unit at the core Bridge's CP, there is no need for a congestion notification and encapsulation interworking function. For example, a PBN in which the C-TAGs are not carried across the core needs no interworking function.

b) In a network where an encapsulation comprises the first octets of the mac_service_data_unit at the core Bridge's CP, a congestion notification and encapsulation interworking function is required. It is useful to make a further distinction, in this case:

   1) The MAC addresses of Ports in the Bridges where the encapsulation and decapsulation functions are performed are the destination and source addresses of frames crossing the core Bridges. For example, in a PBBN, the I-TAG, and perhaps an S-TAG and/or a C-TAG as well, can be present as the first octets of the mac_service_data_unit, and the source_address and destination_address parameters visible to the core Bridge's CP are the addresses of PIPs in BEBs.

   2) In other networks, although an encapsulation is in the first octets of the mac_service_data_unit at the core Bridge's CP, the source and destination MAC addresses are not altered by the encapsulation and decapsulation operations. For example, in a PBN in which both a C-TAG and an S-TAG are carried across the core, the C-TAG occupies the first octets of the mac_service_data_unit as seen by a core Bridge's CP.

In either type of network covered by case b), the core Bridge's CP is configured by the network administrator to return, in the Encapsulated MSDU field of the CNM PDU (33.4.10), the leading octets of the mac_service_data_unit of the data frame triggering transmission of the CNM. Since the CN-TAG of the data frame, if present, is buried behind encapsulations unknown to the CP, when the CN-TAG and CNM are built according to 32.9.4, the Flow ID returned in the CN-TAG of the CNM is filled with 0. The network administrator configures the CP to return at least enough octets of the data frame's mac_service_data_unit to include the CN-TAG of the original data frame transmitted by the RP.

The difference between case 1) and case 2), preceding, lies in the means used by the Port containing the congestion notification and encapsulation interworking function to recognize the CNM in order to translate it. In case 1), the CNM is addressed to that Port, and has a CN-TAG and the CNM encapsulation, instead of a data frame tag and encapsulation. In case 2), the only reliable indicator of a CNM that needs to be transformed, as opposed for example, to a CNM returned by the destination end station's CP, can be the presence of an encapsulation known to the interworking function in the Encapsulated MSDU field (33.4.10) of the CNM PDU.

When the CNM generated by the core Bridge's CP reaches a congestion notification and encapsulation interworking function, that interworking function uses the information in the CNM PDU, including the encapsulated data frame information, to construct a CN-TAG and CNM PDU to send to the RP. The steps taken are as follows:

c) In case 1), where the CNM is returned to the MAC address of the interworking function's Port, the destination_address parameter is obtained from the appropriate source address found in the Encapsulated MSDU field, and the source_address parameter is a MAC address belonging to the Bridge containing the interworking function, and valid in the context of the newly generated CNM, for example, a management port address.

d) In case 2), where the CNM is recognized by the presence of the encapsulation in the Encapsulated MSDU field, the source_address, and destination_address parameters are unchanged.

e) The vlan_identifier is obtained from the Encapsulated MSDU field.

f) The drop_eligible parameter is False.

g) The priority parameter used is the value configured for a CP on a Port in the Bridge in which the interworking function resides, and through which the CNM passes.

h) The Encapsulated priority field (33.4.7) is obtained from the Encapsulated MSDU field, or if not present there, the Encapsulated priority is left unchanged.

NOTE—In spite of the provisions for CND defense in this clause, it is possible for a network administrator to configure a network so that the priority of a CCF data frame is not preserved. For example, in a PBN, two CNPVs could be mapped to the same S-TAG priority, and the C-TAG not configured to be carried across the network. In that case, an end station with an RP on each of those CNPVs, and that does not distinguish between those RPs using CN-TAGs, would be unable to assign returned CNMs to the right RP. At least some of its CCFs would not be constrained, and uncontrolled congestion would likely result. It is therefore recommended that the CN-TAG be included across a PBN, or that each CNPV be mapped to a separate priority in the backbone.

i) If a CN-TAG is found in the Encapsulated MSDU, its Flow ID is copied to the CN-TAG of the newly generated CNM, else 0 is used for that CN-TAG's Flow ID.

j) The encapsulation in the Encapsulated MSDU field of the CNM PDU, up to and including the CN-TAG (which is not necessarily present), is elided, the remainder (if any) of the Encapsulated MSDU field moved up to the first octets of the field, and the Encapsulated MSDU length field reduced accordingly.

33. Encoding of congestion notification PDUs

This clause specifies the method of encoding congestion notification PDUs. The specifications include the following:

a) The general structure and encoding of congestion notification PDUs (33.1)
b) The format used for the CN-TAG (33.2)
c) The encapsulation used for a CNM (33.3)
d) The format used for the CNM (33.4)

The format of the IEEE 802.1AB Type Length Value (TLV) used to signal that a VLAN Bridge or end station is congestion aware, and the state of its CND defense mode, is specified in D.2.7.

NOTE—Clause 30 introduces the principles of congestion notification operation and the network architectural concepts that support it. Clause 31 breaks down the congestion notification entities into their components. Clause 32 specifies the protocols operated by these components.

33.1 Structure, representation, and encoding

All congestion notification PDUs contain an integral number of octets.

The octets in a congestion notification PDU are numbered starting from 1 and increasing in the order they are put into the MSDU that accompanies a request to or indication from the instance of the MAC Internal Sublayer Service (ISS or EISS) used by a congestion notification entity.

The bits in an octet are numbered from 1 to 8 in order of increasing bit significance, where 1 is the LSB in the octet.

Where octets and bits within a congestion notification PDU are represented using a diagram, octets shown higher on the page than subsequent octets and octets shown to the left of subsequent octets at the same height on the page are lower numbered; bits shown to the left of other bits within the same octet are higher numbered.

Where two or more consecutive octets are represented as hexadecimal values, lower numbered octet(s) are shown to the left and each octet following the first is preceded by a hyphen, e.g., 01-80-C2-00-00-00.

When consecutive octets are used to encode a binary number, the lower octet number has the more significant value. When consecutive bits within an octet are used to encode a binary number, the higher bit number has the most significant value. When bits within consecutive octets are used to encode a binary number, the lower octet number composes the more significant bits of the number. A flag is encoded as a single bit, and is set (TRUE) if the bit takes the value 1, and clear (FALSE) otherwise. The remaining bits within the octet can be used to encode other protocol fields.

33.2 CN-TAG format

The means for identifying CN-TAG PDUs consist of two octets containing the EtherType value shown (in hexadecimal notation) in Table 33-1.

In a VLAN Bridge, the shim that supports the EISS (IEEE Std 802.1AC, 6.8, Figure 22-4) is below the Queuing shim (8.6.6, 8.6.7, 8.6.8, 31.1.1). The CN-TAG is examined by the CP, which is part of the Queuing shim. Therefore, the CN-TAG will be further from the source_address and destination_address fields, and closer to the end of the frame, than a VLAN tag added by 6.8, if any. In order for a Bridge to be able to recognize the CN-TAG in a data frame, an end station shall insert the CN-TAG and VLAN tag in the relative order required by a Bridge: addresses, VLAN tag, CN-TAG, data.[47]

Table 33-1—CN-TAG Encapsulation

	Octet	Length
Tag EtherType (22-E9)	1	2
Flow Identifier	3	2

33.2.1 Flow Identifier

The meaning and encoding of the Flow Identifier field are not specified by this standard. A CP shall not interpret the value in a Flow Identifier field. The Flow ID returned in the CN-TAG of a CNM is used by an end station's CNM demultiplexer (31.2.5) to identify the RP, the Flow queue, or a group of one or more individual flows, from which was transmitted the data frame that triggered the CNM.

33.3 Congestion Notification Message (CNM)

The means for identifying CNM PDUs consist of two octets containing the EtherType value shown (in hexadecimal notation) in Table 33-2.

Table 33-2—CNM Encapsulation

	Octet	Length
PDU EtherType (22-E7)	1	2
CNM PDU	3	24 to 88

33.4 Congestion Notification Message PDU format

The format of a Congestion Notification Message (CNM) PDU is illustrated in Table 33-3. If the frame that triggered the transmission of the CNM carried a CN-TAG, then that CN-TAG is retained in the frame carrying the CNM PDU; otherwise, a CN-TAG with a FlowID of 0 is used in the frame carrying the CNM PDU.

33.4.1 Version

This field, 4 bits in length, shall be transmitted with the value 0, and shall be ignored on receipt. The Version field occupies the most significant bits of the first octet of the CNM PDU.

33.4.2 ReservedV

This field, 6 bits in length, shall be transmitted with the value 0, and shall be ignored on receipt. The ReservedV field occupies the least significant 4 bits of the first octet, and the most significant 2 bits of the second octet, of the CNM PDU.

[47] There are other tags, e.g., the IEEE 802.1AE MAC Security tag, not included in this abbreviated list.

Table 33-3—Congestion Notification Message PDU

	Octet	Length
Version	1	4 bits
ReservedV	1, 2	6 bits
Quantized Feedback	2	6 bits
Congestion Point Identifier	3	8
cnmQOffset	11	2
cnmQDelta	13	2
Encapsulated priority	15	2
Encapsulated destination MAC address	17	6
Encapsulated MSDU length	23	2
Encapsulated MSDU	25	0–64

33.4.3 Quantized Feedback

This field, 6 bits in length, contains the Quantized Feedback value calculated by the CP's EM_UNITDATA.request (parameters) procedure (32.9.3). The Quantized Feedback field occupies the least significant bits of the first two octets of the CNM PDU.

33.4.4 Congestion Point Identifier

This field, 8 octets in length, uniquely identifies the CP that triggered the transmission of this Congestion Notification Message PDU format within the CND. Because the transmitting system can format the Congestion Point Identifier (CPID) in any manner, a receiving RP shall not assign any meaning to subfields within a CPID.

NOTE—Making the CPID 8 octets long removes the connection between CP identity and the source MAC address of the CNM PDU. One way to achieve the requirements for uniqueness of the CPID would be to use a Port's MAC address as the high-order 6 octets of the CPID, and use the low-order two octets of the CPID to hold the priority of the CP's queue and/or an indication of the physical port.

33.4.5 cnmQOffset

The twos-complement signed integer value of (–1 × cpQOffset) (32.8.7) of the transmitting CP in units of 64 octets. This standard does not specify whether cpQOffset is rounded or truncated to obtain cnmQOffset. If the value of cpQOffset is less than –32 768, a value of –32 768 is used in cpQOffset, and if greater than 32 767, then 32 767 is used.

33.4.6 cnmQDelta

The twos-complement signed integer value of the transmitting CP's cpQDelta (32.8.8) in units of 64 octets. This standard does not specify whether cpQDelta is rounded or truncated to obtain cnmQDelta. If the value of cpQDelta is less than –32 768, a value of –32 768 is used in cnmQDelta, and if greater than 32 767, then 32 767 is used.

NOTE—Although cnmQDelta is not used by the RP, it is included in the CNM PDU to aid the network administrator when adjusting configuration parameters.

33.4.7 Encapsulated priority

This field, 2 octets in length, contains the priority parameter of the frame that triggered the transmission of this CNM in the most significant 3 bits of the field. The remaining bits of the field are transmitted as 0, and ignored on receipt.

33.4.8 Encapsulated destination MAC address

This field, 6 octets in length, contains the destination_mac_address parameter of the frame that triggered the transmission of this CNM.

33.4.9 Encapsulated MSDU length

This field, 2 octets in length, contains the number of octets returned in the Encapsulated MSDU field (33.4.10).

33.4.10 Encapsulated MSDU

This field, a maximum of 64 octets in length, contains the initial octets of the mac_service_data_unit of the frame that triggered the transmission of this CNM.

33.4.11 CNM Validation

A CNM PDU received by a CNM demultiplexer (31.2.5) shall be considered invalid and be discarded if the following condition is TRUE:

a) There are fewer than 24 octets in the mac_service_data_unit.

A CNM PDU received by a CNM demultiplexer (31.2.5) may be considered invalid and be discarded if the following condition is TRUE:

b) The CNM PDU has no CN-TAG.

NOTE 1—The variable cnpdAcceptsCnTag (32.4.10), when set FALSE in an end station, indicates to the neighboring Bridge that the CN-TAG is to be removed from all frames, including CNMs, transmitted to the end station. It is not recommended that an end station set cnpdAcceptsCnTag to FALSE if this would result in the end station discarding CNMs for lack of a CN-TAG.

The following condition shall not cause a received CNM PDU to be considered invalid:

c) There are nonzero bits in the Version (33.4.1) or ReservedV (33.4.2).

NOTE 2—These rules permit information to be added to the CNM PDU following the Encapsulated MSDU field (33.4.10) in later revisions of this standard.

34. Forwarding and Queuing Enhancements for time-sensitive streams (FQTSS)

34.1 Overview

This clause describes a set of tools that can be used to support the forwarding and queuing requirements of time-sensitive streams. In this context, a "time-sensitive stream" is taken to be a stream (flow) of traffic, transmitted from a single source station (Talker), destined for one or more destination stations (Listeners), where the traffic is sensitive to timely delivery, and in particular, requires transmission latency to be bounded. Such streams include video or audio data streams, where there is a desire to limit the amount of buffering required in the receiving station (Listener). The description in this clause (Clause 34) applies when the transmission gates for scheduled traffic (8.6.8.4) are continuously open, as closing those gates affects the availability of bandwidth.

NOTE 1—An example of the need to support time-sensitive stream requirements would be a live performance where a video image of the performance is simultaneously projected on a screen in the auditorium, and it is desirable for the sound and image to be "in sync" with the performance.

The term "stream reservation class" (SR class) refers to a traffic class whose bandwidth can be reserved for time-sensitive streams using the Stream Reservation Protocol (SRP). FQTSS specifies the relationship between an SR class and the underlying tools of this standard, such as traffic class, priority, and transmission selection.

NOTE 2—The FQTSS functions described in this clause are intended for use with SRP, with the exception of adminIdleSlope [item c) in 34.3]. The adminIdleSlope parameter is intended for TSN configuration models that do not use SRP. In the fully centralized model of TSN configuration (46.1.3.3), the CNC entity can use adminIdleSlope to reserve bandwidth for a traffic class.

In order to address the needs of such traffic in Bridges, the following are provided:

a) A means of detecting the boundary between a set of Bridges that support SRP (an SRP domain) and surrounding Bridges that do not support SRP. This mechanism is described in 34.2.
b) A set of bandwidth availability parameters for each port that are used to record the maximum bandwidth available to a given outbound queue, and the actual bandwidth reserved, for that queue. These parameters are described in 34.3.
c) A discussion of the relationship between the size of the layer 2 "payload" (the MSDU) carried in a frame and how that relates to the actual bandwidth that will be consumed when that MSDU is transmitted on a particular Port (34.4).
d) Specifications for the default configuration of SR classes, including the mapping of the priorities associated with received frames onto the traffic classes available on the transmission Ports of a Bridge (34.5).
e) Specifications for use of transmission selection algorithms for SR classes (34.6).

34.2 Detection of SRP domains

The concepts of time-sensitive streams, the Stream Reservation Protocol (SRP), and the traffic forwarding and shaping functions that support stream transmission (e.g., 8.6.8.1), rely on the ability of each Bridge to detect whether each of its Ports is at the edge of a region of connected Bridges that support SRP on a particular priority, so that the Priority Code Point values associated with traffic entering an *SRP domain* (3.260) can be properly regenerated at the boundary of the domain, as described in 6.9.4.

Bridges detect the edge of an SRP domain by observing SRP behavior. If a Bridge receives SRP registrations using a particular priority, then it is reasonable to believe that they are being received from an SRP-capable device; the SRP engine can therefore signal which Ports of a Bridge are at the boundary of an SRP domain. The per-Port, per-SR class, *SRPdomainBoundaryPort* parameter determines whether a Port is

considered to be at the edge of an SRP domain or within the core of the domain, as defined in 35.1.4. This parameter is controlled by the operation of SRP.

NOTE—SRP domain detection is based on the assumption that a device connected to a Port either is SRP capable for a given SR class, or is not SRP capable for that SR class. SRP provides a boundary detection mechanism through the exchange of MSRPDUs; the boundary of a domain therefore expands to include Ports as SRP attributes are declared. The position of the domain boundary has no effect on the transmission of SRP frames; rather, it reflects where SRP activity is occurring. Ports are removed from the SRP domain when they are removed from the active topology.

34.3 The bandwidth availability parameters

The following bandwidth availability parameters exist for each Port, and for each traffic class, N, that is configured as an SR class (34.5):

a) ***portTransmitRate*** as defined in 8.6.8.2;
b) ***deltaBandwidth(N)***: The bandwidth, represented as a percentage of *portTransmitRate,* that can be reserved by SRP for use by the queue associated with traffic class N. The interpretation of *deltaBandwidth(N)* is determined by the value of the associated *lockClassBandwidth(N)* as specified in 34.3.1 and 34.3.3.
c) ***adminIdleSlope(N)***: The bandwidth, in bits per second, that has been requested by management to be reserved for use by the queue associated with traffic class N. If SRP is in operation for traffic class N, this parameter has no effect. If SRP is not in operation for traffic class N, then the value of *operIdleSlope(N)* is always equal to the value of *adminIdleSlope(N)*.
d) ***operIdleSlope(N)***: The actual bandwidth, in bits per second, that is currently reserved for use by the queue associated with traffic class N (see 34.6.1 and 34.6.2).
e) ***classMeasurementInterval(N)***: The interval of time, in seconds, over which SRP's TSpec (34.4, 35.2.2.8.4) is measured for traffic class N at the Talker.
f) ***lockClassBandwidth(N)***: The Boolean parameter that determines the interpretation of *deltaBandwidth(N)*. For the value false (default), *deltaBandwidth(N)* is specified in 34.3.1. For the value true, *deltaBandwidth(N)* is specified in 34.3.3.

In all cases, bandwidth is defined in terms of the actual bandwidth consumed when frames are transmitted through the Port, not the size of the MSDU "payload" carried within those frames. Subclause 34.4 discusses the relationship between MSDU size and actual bandwidth consumed. The bandwidth availability parameters and their use as described in this clause (Clause 34) do not take into account any interruption to bandwidth availability resulting from the operation of stream gates (8.6.5.2).

34.3.1 deltaBandwidth when lockClassBandwidth is false

When ***lockClassBandwidth(N)*** is false, ***deltaBandwidth(N)*** is the additional bandwidth, represented as a percentage of ***portTransmitRate***, that can be reserved by SRP for use by the queue associated with traffic class N, in addition to the ***deltaBandwidth(N)*** values associated with higher priority queues with ***lockClassBandwidth(N)*** false. For a given traffic class N, the total bandwidth that can be reserved is the sum of the ***deltaBandwidth*** values for traffic class N and all higher traffic classes with ***lockClassBandwidth(N)*** false, minus any bandwidth reserved by higher traffic classes (i.e., configured as SR classes).

The default value of ***lockClassBandwidth(N)*** is false. This default can be changed using the managed objects of the Bandwidth Availability Parameter Table (12.20.1).

The default value of *deltaBandwidth(N)* for the highest numbered traffic class supported is 75%, and for any lower numbered traffic classes, the default value is 0%. The *deltaBandwidth(N)* for a given *N*, plus the *deltaBandwidth(N)* values for any higher priority queues (larger values of *N*) defines the total percentage of the Port's bandwidth that can be reserved for that queue and all higher priority queues. For the highest priority queue, this means that the maximum value of *operIdleSlope(N)* is *deltaBandwidth(N)*% of

portTransmitRate. However, if *operIdleSlope(N)* is actually less than this maximum value, any lower priority queue with *lockClassBandwidth(N)* false can make use of the reservable bandwidth that is unused by the higher priority queue. So, for queue $N-1$, the maximum value of (*operIdleSlope(N)* + *operIdleSlope(N – 1)*) is (*deltaBandwidth(N)* + *deltaBandwidth(N – 1)*)% of *portTransmitRate*.

NOTE 1—For example, suppose two queues, 3 and 2, are configured as SR classes A and B, respectively. Suppose *deltaBandwidth(3)* for SR class A is currently 20%, and *deltaBandwidth(2)* for SR class B is currently 30%, and *lockClassBandwith* is false for both. If *operIdleSlope(3)* is currently 10% of *portTransmitRate*, then half of queue 3's maximum allocation is unused, and the maximum value of *operIdleSlope(2)* is therefore currently 40% of *portTransmitRate*. However, if *operIdleSlope(3)* increases to the full 20% that it is entitled to use, the maximum value of *operIdleSlope(2)* reduces to 30% of *portTransmitRate*.

NOTE 2—The sum of the *deltaBandwidth(N)* values for all values of N should be chosen such that there is sufficient bandwidth available for any nonreserved (best-effort, strict-priority) traffic; the default values are chosen such that the sum of the *deltaBandwidth(N)* values is 75%, so no more than 75% of the Port's available bandwidth is permitted to be reserved. This ensures that when using default settings, there is at least 25% of the Port's bandwidth available for nonreserved traffic. However, as these default settings may be inappropriate for some situations (e.g., links that offer very high bandwidth, or networks with very low levels of nonreserved traffic), they can be modified by management.

34.3.2 deltaBandwidth when lockClassBandwidth is true

When *lockClassBandwidth(N)* is true, *deltaBandwidth(N)* is the maximum bandwidth, represented as a percentage of *portTransmitRate*, that can be reserved by SRP for use by the queue associated with traffic class *N*. The bandwidth limit of *deltaBandwidth(N)* is not related to higher or lower priority traffic classes (i.e., it is not truly a delta).

NOTE—For example, suppose two queues, 3 and 2, are configured as SR classes A and B, respectively. Suppose *deltaBandwidth(3)* for SR class A is currently 20%, *deltaBandwidth(2)* for SR class B is currently 30%, and *lockClassBandwidth* is true for both. If *operIdleSlope(3)* is currently 10% of *portTransmitRate*, then half of queue 3's maximum allocation is unused. Nevertheless, the maximum value of *operIdleSlope(2)* remains 30% of *portTransmitRate*. The value of *operIdleSlope(2)* cannot increase to 40%, because 20% is locked to use by *operIdleSlope(3)*.

34.3.3 Bandwidth availability parameter management

The values of *deltaBandwidth(N)* and *adminIdleSlope(N)* can be changed by management, using the management operations defined in 12.20. If the stream reservation mechanisms defined in SRP are supported, then the values of *operIdleSlope(N)* are determined solely by the operation of SRP. If the stream reservation mechanisms defined in SRP are not supported, then the values of *operIdleSlope(N)* are equal to the values requested by management in the corresponding *adminIdleSlope(N)* parameters.

It is possible for the value of *portTransmitRate* for a Port to change as a result of the normal operation of the underlying MAC Service (e.g., as a result of the operation of IEEE 802.1AX Link Aggregation, or as a result of dynamic changes in bandwidth of the physical layer technology itself, as can occur in wireless LAN technologies); it is also possible for management action to change the values of *deltaBandwidth(N)* for a Port. In either case, the consequence could be one of the following:

a) The sum of the *operIdleSlope(N)* values for the Port could now exceed the total reservable bandwidth allowed for the Port, or the *operIdleSlope(N)* value for a given queue could now exceed the reservable bandwidth allowed for the queue, as defined in 34.3.1 and 34.3.2. Consequently, there could be streams currently active on the Port that can no longer be supported.
b) The bandwidth now available to a given queue could mean that there are streams that are currently inactive that could be supported on the Port.
c) Active streams that continue to be supported after the change could see their latency guarantee change.

In either case, corrective action, either by management or by the stream reservation mechanisms defined in SRP, is required in order to restore the parameters to a consistent set of values. In order to indicate that there have been changes in the bandwidth availability database, a signal, *bandwidthAvailabilityChanged*, is

generated for each Port whenever the bandwidth availability parameters *portTransmitRate* or *deltaBandwidth(N)* are changed; this signal is used by SRP to trigger recalculation of the set of streams that can be reserved on the Port.

NOTE—During recalculation of stream reservations, the Bridge might be temporarily unable to honor bandwidth reservation commitments or forward best-effort traffic.

34.4 Deriving actual bandwidth requirements from the size of the MSDU

The forwarding and queuing mechanisms defined in this clause use bandwidth parameters that are defined in terms of the actual bandwidth used when frames are transmitted on the medium that supports the MAC Service available through the Port. In contrast, the SRP makes use of a traffic specification (TSpec) for each stream that defines the maximum number of bits per frame (*MaxFrameSize*), of the mac_service_data_unit parameter that is relayed by the relay function of the Bridge, and a maximum frame rate (*MaxIntervalFrames*), in frames per class measurement interval, for that stream; i.e., the TSpec takes no account of the per-frame overhead associated with transmitting the MSDU over a given medium. However, when SRP determines the value to be used for the ***operIdleSlope(N)*** parameter associated with a given queue, it is necessary for this value to include the per-frame overhead that will be incurred when frames are transmitted on that Port.

NOTE 1—The frame rate in a TSpec is measured over the classMeasurementInterval (34.3) that depends upon the SR class associated with the stream. Default values for classMeasurementInterval are specified in 34.5.

For the purposes of calculating the bandwidth consumption of a stream, it is assumed that the stream data is essentially of constant size and transmission rate, so these maxima can be used to directly define an assumed maximum payload size and the maximum frame rate in frames per second; i.e.,

$$\textbf{\textit{assumedPayloadSize}} = MaxFrameSize \tag{34-1}$$

$$maxFrameRate = MaxIntervalFrames \times (1/classMeasurementInterval) \tag{34-2}$$

where *classMeasurementInterval* is measured in seconds.

NOTE 2—As stated, the calculation of bandwidth from TSpec parameters assumes that the stream data is essentially of constant frame size, and hence, the approximations shown in this section are valid. If the data varies significantly in frame size, then the calculation of per-frame overhead using these assumptions could be significantly in error.

From this, and also from local knowledge of the protocol stack that supports the Bridge Port, it is possible to determine the overhead that is added to the per-frame MSDU payload when a frame is transmitted. There are at least the following sources of per-frame overhead:

a) Any VLAN tags and security tags (see IEEE Std 802.1AE) that are added to the layer 2 payload as it passes through the various service interfaces in the Port's protocol stack.
b) The MAC framing (header and trailer octets, plus any padding octets that are required to meet minimum frame size limitations) that is added by the underlying MAC Service.
c) Any physical layer overhead, such as preamble characters and inter-frame gaps.

The precise per-frame overhead will therefore depend upon the protocol stack and the underlying MAC technology.

The actual bandwidth needed to support a given stream is therefore defined as follows [using *assumedPayloadSize* from Equation (34-1)]:

$$actualBandwidth = (perFrameOverhead + assumedPayloadSize) \times maxFrameRate \tag{34-3}$$

34.5 Default SR class configuration

This subclause (34.5) makes traffic class, priority, transmission selection algorithm, and classMeasurementInterval recommendations for use with FQTSS.

The recommended mappings of priorities to traffic classes meet the following constraints:

a) Priority values that correspond to SR classes are mapped onto traffic classes that support the credit-based shaper algorithm as the transmission selection algorithm.
b) Traffic classes that support the credit-based shaper algorithm have a higher priority than traffic classes that support the strict priority (or any other) transmission selection algorithm.
c) At least one traffic class supports the credit-based shaper algorithm, and at least one traffic class supports the strict priority transmission selection algorithm.

NOTE 1—The constraint that there is at least one traffic class that supports the strict priority transmission selection ensures that there is at least one traffic class that can support traffic that is not subject to bandwidth reservation, such as "best effort" traffic.

The recommended priority to traffic class mappings for a network that supports SR class A (using priority 3) and SR class B (using priority 2) are shown in Table 34-1. The recommended priority to traffic class mappings for a system that supports only SR class B (using priority 2) are shown in Table 34-2. These mappings can be changed using the managed objects of the Traffic Class Table for each Port (12.6.3).

The corresponding configuration for the Transmission Selection Algorithm Table (see 8.6.8) is that the traffic classes that are shaded in the tables are configured to use the credit-based shaper algorithm, and the remaining traffic classes are configured to use the strict priority algorithm. Traffic classes that are shaded correspond to default SR classes. These defaults can be changed using the managed objects of the Transmission Selection Algorithm Table (12.20.2).

Table 34-1—Default priority to traffic class mappings for SR classes A and B

		Number of available traffic classes						
		2	**3**	**4**	**5**	**6**	**7**	**8**
Priority	0 (Default)	0	0	0	0	0	0	1
	1	0	0	0	0	0	0	0
	2	1	1	2	3	4	5	6
	3	1	2	3	4	5	6	7
	4	0	0	1	1	1	1	2
	5	0	0	1	1	1	2	3
	6	0	0	1	2	2	3	4
	7	0	0	1	2	3	4	5

NOTE 2—The mapping shown in Table 34-1 for the case of only two available traffic classes maps two SR classes to a single traffic class. While this is a permissible configuration, in general it is desirable, and in some applications, can be a requirement, to assign SR classes to distinct traffic classes, as is done in this table for the cases where three or more traffic classes are available. The mappings shown deal only with one or two supported SR classes; a similar mapping strategy can be adopted if more than two SR classes are supported.

Table 34-2—Default priority to traffic class mappings for SR class B only

		Number of available traffic classes						
		2	**3**	**4**	**5**	**6**	**7**	**8**
Priority	0 (Default)	0	0	0	0	0	1	1
	1	0	0	0	0	0	0	0
	2	1	2	3	4	5	6	7
	3	0	0	0	1	1	2	2
	4	0	1	1	2	2	3	3
	5	0	1	1	2	2	3	4
	6	0	1	2	3	3	4	5
	7	0	1	2	3	4	5	6

Table 34-1 and Table 34-2 specify a default configuration of SR class A as priority 3, and SR class B as priority 2. These defaults can be changed using the managed objects of the SR Class to Priority Mapping Table (12.20.4).

The default classMeasurementInterval (34.3) of SR class A is 125 µs. The default classMeasurementInterval of SR class B is 250 µs. These defaults can be changed using the managed objects of the Bandwidth Availability Parameter Table (12.20.1).

34.6 Transmission selection

Transmission selection (8.6.8) is used to shape the transmission of a Stream's frames in accordance with the bandwidth that has been reserved on a given outbound queue for a traffic class.

The following transmission selection algorithm shall be supported for FQTSS, configured as the default for SR class A and/or B:

a) Credit-based shaper algorithm, specified in 8.6.8.2

The following transmission selection algorithm may be supported for FQTSS, configured using the managed objects of the Transmission Selection Algorithm Table (12.20.2):

a) Strict priority algorithm, specified in 8.6.8.1

The following transmission technique may be supported for FQTSS, configured using the managed objects for scheduled traffic (12.29):

a) Scheduled traffic, specified in 8.6.8.4

34.6.1 Credit-based shaper

The ***operIdleSlope(N)*** parameter (34.3) is used by the credit-based shaper algorithm (8.6.8.2) as its idleSlope for the corresponding queue, to shape outbound traffic.

The ***operIdleSlope(N)*** parameter is also used to reserve space in the queue of the traffic class that is assigned to the SR class.

In order for an end station to successfully participate in the transmission and reception of time-sensitive streams, it is necessary for their behavior to be compatible with the operation of the forwarding and queuing mechanisms employed in Bridges. The requirements for end stations that participate as "Talkers"—i.e., sources of time-sensitive streams—are different from the requirements that apply to "Listeners"—i.e., the destination station(s) for the streams.

34.6.1.1 Talker behavior

In order for Talker-originated data streams to make use of the credit-based shaper behavior in Bridges, it is a requirement for a Talker to use the priorities that the Bridges in the network recognize as being associated with SR classes exclusively for transmitting stream data. It is also necessary for the Talker, and the Bridges in the path to the Listener(s), to have a common view of the bandwidth required in order to transmit the Talker's streams, and for that bandwidth to be reserved along the path to the Listener(s). This latter requirement can be met by means of stream reservation mechanisms, such as defined in SRP, or by other management means.

End stations that are Talkers shall exhibit transmission behavior for frames that are part of time-sensitive streams that is consistent with the operation of the credit-based shaper algorithm, both in terms of the way they transmit frames that are part of an individual data stream, and in terms of the way they transmit stream data frames from a Port. In effect, the queuing model for a Talker Port, and for a given priority, can be considered to look like Figure 34-1.

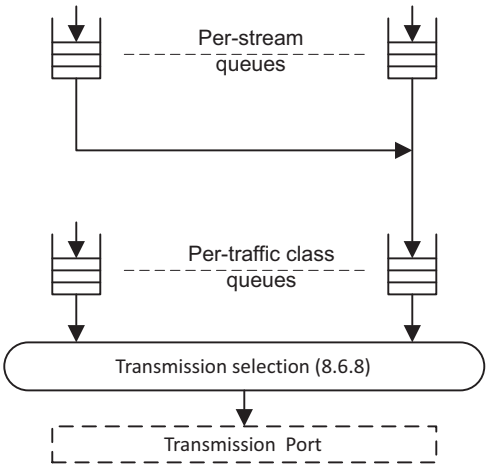

Figure 34-1—Queuing model for a Talker station

The Talker places frames into the queue associated with an individual stream based on the Tspec for that stream; i.e., during each *classMeasurementInterval,* it can place up to *MaxIntervalFrames* data frames, each no longer than *MaxFrameSize* into that stream's queue.

The queue associated with each individual stream uses the credit-based shaper algorithm, with the *idleSlope* set to the bandwidth requirement of the stream on that transmission Port, as the means of determining the rate at which data frames for that stream are placed in the outbound queue for the priority that the stream is using. The outbound queue for that priority, in turn, makes use of the credit-based shaper algorithm, with the *idleSlope* set to the sum of the *idleSlope* values for all streams using that priority on that transmission Port, as the means of determining the rate at which data frames for that stream are selected for transmission.

Transmission selection in a Talker operates in the same way as in a Bridge; from this point of view, a Talker can be thought of as if it is a single-port Bridge.

For streams that make use of SR class A or SR class B, it is a requirement that the rate at which frames for any given stream are selected for placement in its per-stream queue does not exceed the bandwidth reserved for the stream, measured over the *classMeasurementInterval* (34.3) for the SR class. For some combinations of stream bandwidth requirement and transmission Port data rate, this can place a limit on the frame size that can be used when transmitting stream data.

NOTE—The sole implication of the *classMeasurementInterval* is its effect on frame size, because the shaper behavior itself is independent of the *classMeasurementInterval*. The intent in limiting the *classMeasurementInterval* is to limit frame size, as this is a major contribution to the latency experienced by a frame in transit through a time-sensitive network (see discussion in Annex L).

34.6.1.2 Listener behavior

The primary requirement for a Listener end station using the credit-based shaper is that it is capable of buffering the amount of data that could be transmitted for a stream during a time period equivalent to the accumulated maximum jitter that could be experienced by stream data frames in transmission between Talker and Listener. From the point of view of the specification of the forwarding and queuing requirements for time-sensitive streams, it is assumed that the Listener will assess the buffering required for a stream as part of the stream bandwidth reservation mechanisms employed by the implementation.

34.6.2 Strict priority

The ***operIdleSlope(N)*** parameter (34.3) represents the total outbound bandwidth for the queue of traffic class N, and ***operIdleSlope(N)*** shall be used to reserve space in the queue of the associated traffic class N.

NOTE 1—The *operIdleSlope(N)* parameter is not used by the algorithm for transmission selection (8.6.8.1).

When SRP is used for reservation of a stream, the egress Port that uses strict priority will place frames into its outbound queue based on the Tspec for that Stream. The TSpecs of all Streams that egress the Port are used to compute the ***operIdleSlope(N)***.

When SRP is not used, the worst-case bandwidth for traffic class N is computed by a management client (e.g., CNC of 46.1.3.3, using TSpecs from the CUC) for the queue of the associated traffic class N. The management client uses ***adminIdleSlope(N)*** to configure this bandwidth in the station (12.20.1). Since ***operIdleSlope(N)*** is equal to ***adminIdleSlope(N), operIdleSlope(N)*** is used to reserve space in the queue of the associated traffic class N. Since the priority associated with traffic class N is not using SRP, that priority does not need to be configured as an SR class (i.e., assigned an SRclassID using 12.20.4).

NOTE 2—As an example of a traffic class configured using *adminIdleSlope(N)*, consider a traffic class that is protected using scheduled traffic (8.6.8.4). This protected traffic class can use the strict priority algorithm. Traffic in the protected window requires queue reservation in order to ensure that adequate storage exists in its queue. The CNC entity of 46.1.3.3 can use *adminIdleSlope(N)* to ensure that the queue for the protected traffic class is of sufficient size.

NOTE 3—Although *adminIdleSlope(N)* is specified as bits per second, with regard to reserving queue space for a shorter interval of time, it is best to assume that *adminIdleSlope(N)* is uniform over the entire second. For example, for a traffic class that is protected using scheduled traffic (8.6.8.4), if AdminCycleTime is 1 ms, *adminIdleSlope(N)* is divided by 1000 to determine the worst-case traffic for that AdminCycleTime.

34.6.3 Scheduled traffic

When SRP uses Centralized Network Configuration (CNC), scheduled traffic (8.6.8.4) can be used in a Talker as well as the Bridges to each Listener. For information, refer to the specifications for externalControl TRUE in 35.2.2.10.

When SRP is fully distributed (externalControl FALSE in 35.2.2.10), use of scheduled traffic in Bridges is not specified for SRP's Streams. If scheduled traffic is used in a Talker, that Talker appends the TSpecTimeAware TLV to its Talker Advertise. If the nearest Bridge supports the optional capability of translating scheduled traffic in the Talker to the transmission selection used in Bridges (i.e., 34.6.1 or 34.6.2), the nearest Bridge propagates Talker Advertise. As specified in 35.2.2.10.6, if the nearest Bridge does not support the TSpecTimeAware TLV, the nearest Bridge fails the Stream (propagates Talker Failed).

NOTE—For an example using scheduled traffic in a Talker, refer to U.1.1.

35. Stream Reservation Protocol (SRP)

SRP utilizes three signaling protocols [MMRP (10.9), MVRP (Clause 11), and MSRP (35.1)] to establish stream reservations across a bridged network.

Within SRP the Multiple MAC Registration Protocol (MMRP) may be used to control the propagation of Talker registrations throughout the bridged network (35.2.4.3.2).

The Multiple VLAN Registration Protocol (MVRP) is used by end stations and Bridges to declare membership in a VLAN where a Stream is being sourced. This allows the Data Frame Priority [35.2.2.8.5(a)] to be propagated along the path from Talker to Listener(s) in tagged frames. MSRP will not allow Streams to be established across Bridge Ports that are members of the untagged set (8.8.10) for the related VID.

The Multiple Stream Registration Protocol (MSRP) is a signaling protocol that provides end stations with the ability to reserve network resources that will guarantee the transmission and reception of data streams across a network with the requested QoS. These end stations are referred to as Talkers (devices that produce data streams) and Listeners (devices that consume data streams).

Talkers declare attributes that define the stream characteristics so Bridges have the necessary information available when they need to allocate resources for a Stream. Listeners declare attributes that request reception of those same streams. Bridges along the path from Talker to Listener process, possibly adjust, and then forward these MSRP attribute declarations. Bridges associate Talker and Listener attributes via the StreamID present in each of those attributes, which result in changes to the extended filtering services and allocation of internal resources when streams are “brought up.”

In order to establish the SRP domain boundaries, Bridges exchange SR class characteristics with each other and with end stations via MSRP. Neighboring devices that have identical SR class characteristics are considered to be in the same SRP domain and streams may be established between those devices.

MSRP provides a limited error reporting capability that is utilized when a Listener’s request to receive a stream cannot be honored because of some resource constraint within the network.

MSRP also supports the concept of data stream importance. For example, an emergency announcement would be flagged with a more important “rank” than a stream providing background music. This ranking ability allows the Bridges to replace less important streams with more important streams without requiring intervention from the end stations.

There is a considerable body of experience in supplying data streams with guarantees for QoS parameters such as latency, latency variation, or bandwidth. In particular, routers and hosts use the Internet Protocol (IP) and the Resource Reservation Protocol (RSVP, IETF RFC 2205, and IETF RFC 2750) to achieve such guarantees. Supplying guarantees to a data stream requires the following two components:

a) A definition of the resources to be allocated and configured, by end stations and network nodes, for the support of a data stream; and
b) A protocol for end stations to signal to the network nodes their data streams’ requirements, for network nodes to distribute those requirements among each other, and for the network nodes to signal the success or failure of the attempt to reserve resources to support the guarantees.

RSVP supplies the signaling protocol for routers to support data streams in routed networks. This and the following clauses define a protocol to support data streams in bridged networks.

The preceding description of SRP as a signaling protocol corresponds to the Fully distributed model (46.1.3.1) for TSN configuration. SRP also supports the Centralized network/distributed user model (46.1.3.2) for TSN configuration, which can be used to enable enhanced features (see 35.2.2.10). In order to

use the Centralized network/distributed user model, the MRP External Control (12.32.4) feature is enabled in the Nearest Bridge (8.6.3) to each Talker and Listener. Instead of propagating (signaling) through Bridges, SRP messages are exchanged with a Centralized Network Configuration (CNC) entity. The CNC uses remote management protocols (e.g., SNMP, NETCONF) in order to configure Bridges to meet the Stream requirements of each Talker and Listener.

35.1 Multiple Stream Registration Protocol (MSRP)

MSRP supports the reservation of resources for streams, each destined for one or more Listeners, and each from a single source, across a bridged network. Transmitted data that conforms to a successful stream reservation will not be discarded by any Bridge due to congestion on a LAN. In order to propagate requests for reservations, MSRP defines an *MRP application* that provides the Stream resource registration service defined in 35.2.3. MSRP makes use of the MRP Attribute Declaration (MAD) function, which provides the common state machine descriptions defined for use in MRP-based applications. The MRP architecture, and MAD are defined in Clause 10. MSRP defines a new MRP Attribute Propagation (MAP) function, to provide an attribute propagation mechanism.

MSRP propagates registrations for stream reservations in a manner similar to the operation of MMRP (10.9) and MVRP (11.2), which are used for registering Group membership and individual MAC address information, and VLAN membership, respectively. Unlike MMRP and MVRP, however, the registered attributes can be combined, discarded, or otherwise altered, as they are propagated by the participating Bridges.

In order to make and keep QoS guarantees all devices in a bridged network must participate in the signaling and queuing operations required of Bridges. For example, this would include IEEE 802.11 wireless media access points and stations. Thus, MSRP provides a means for Bridges or end stations running MSRP to cooperate both with higher network layers, such as routers or hosts running RSVP, and with lower network layers, such as wireless media.

MSRP is also responsible for establishing the SRP domain boundary for a particular SR class. All systems that support a particular SR class are in the same SRP domain if they use the same priority. An SRP domain boundary exists for an SR class when neighboring devices use different priorities for the SR class.

Figure 35-1 illustrates the architecture of MSRP in the case of a two-Port Bridge and an end station.

The version of MSRP is distinguished by the ProtocolVersion of MRP. ProtocolVersion 0x00 (MSRPv0) is the original version. ProtocolVersion 0x01 (MSRPv1) or higher specifies new AttributeTypes (35.2.2.4) that provide enhanced capabilities. This standard specifies MSRPv1 (35.2.2.1). In order to meet interoperability goals, implementations of this version shall support the original AttributeTypes specified in MSRPv0 as well as the enhanced AttributeTypes. The interoperability goals require a network of mixed MSRPv0 and MSRPv1 end stations and Bridges to provide a quality of service that is as good as or better than a complete MSRPv0 network.

For both MSRPv0 and MSRPv1, each MSRP Participant declares the Domain attribute prior to other MSRP attributes in order to determine SR class boundaries. The MSRPv1 end station or Bridge also uses this Domain exchange to determine the ProtocolVersion of its neighboring MSRP Participant. If the neighbor is MSRPv0, then only the original AttributeTypes are exchanged with that neighbor, although the ProtocolVersion will be set to the value defined in 35.2.2.1 [see item b) in 10.8.3.5]. If the neighbor is MSRPv1, then both original and enhanced AttributeTypes can be exchanged with that neighbor. For a Bridge, this means that it is possible to register an enhanced AttributeType from one Port and propagate and declare that same attribute to another Port as an original AttributeType. To enable this mixture of AtributeTypes, the MSRP Attribute Propagation (35.2.4) specifies the translation from each enhanced AttributeType to its corresponding original AttributeType.

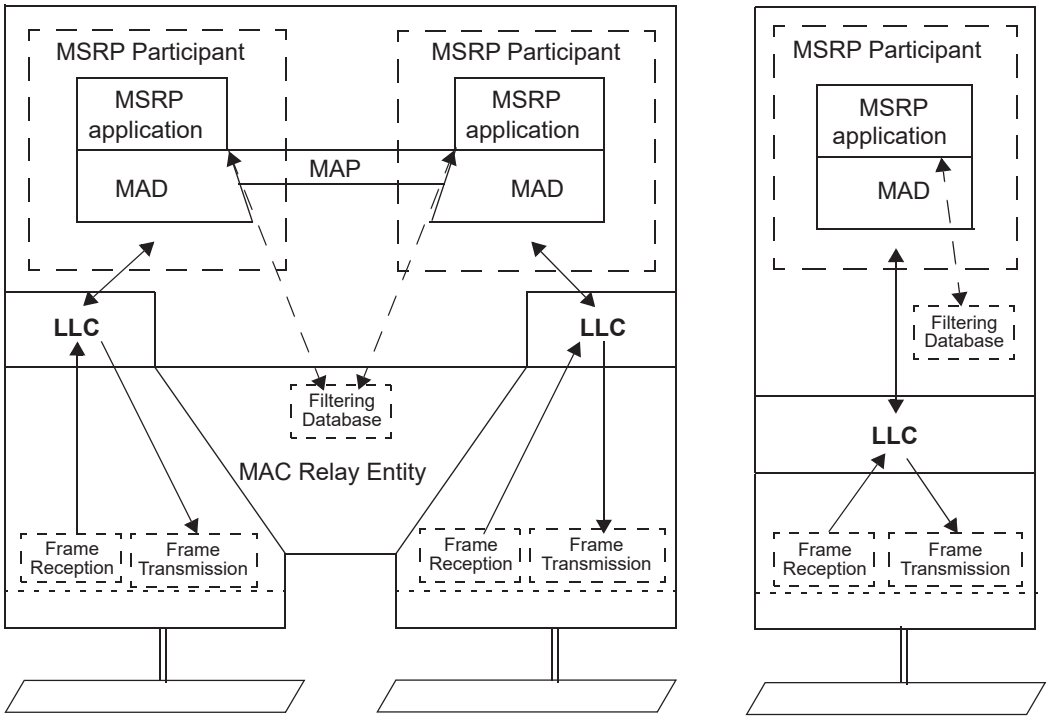

Figure 35-1—Operation of MSRP

For propagation of an MSRP attribute from one Port using MSRPv1 to another Port using MSRPv1, the AttributeType is not changed. This allows original AttributeTypes to propagate through a Bridged Network as is, without translation to enhanced AttributeTypes.

NOTE—MRP (Clause 10) has limitations on the total amount of attribute data that can be exchanged between participants. Therefore, the larger each MSRP attribute's value, the fewer total Streams can be reserved in the network. Due to the enhanced features, the enhanced AttributeType is larger than the original AttributeType. If the Talker and Listeners of a Stream do not need the enhanced features, use of the original AttributeTypes can allow for a larger number of total Streams. If all Talkers and Listeners in the network use original AttributeTypes, the maximum number of Streams in an all-MSRPv1 network is the same as an all-MSRPv0 network.

35.1.1 MSRP and Shared Media

Classic shared media, such as IEEE 802.3 half-duplex Carrier Sense Multiple Access with Collision Detect (CSMA/CD), cannot provide latency or bandwidth guarantees, because their operation depends on random timers. Such media are therefore not supported by MSRP.

There are other shared media where one node on the medium exercises control over access to the medium by the other nodes. For example, an IEEE 802.11 infrastructure wireless medium has a single Access Point (AP) that controls access by the AP and the stations attached to the wireless medium so that some guarantee of latency and bandwidth can be made, subject to frame loss caused by data corruption errors. Similarly, an IEEE 802.3 Ethernet Passive Optical Network has a single Optical Line Terminal (OLT) that controls access to the optical medium by itself and some number of Optical Network Units (ONUs).

Different kinds of shared media use different techniques to allocate opportunities to transmit, and these techniques can have various dependencies on frame sizes, station-to-station vs. station-to-head data paths, or other factors. Rather than introducing the complexities of every such medium into MSRP, this standard takes advantage of the presence of a controlling entity to map medium-specific characteristics to the capabilities of MSRP.

MSRP defines and requires the existence of a Designated MSRP Node (DMN) on any shared medium. This DMN provides the MSRP services for the shared medium and determines each station's ability to receive the MSRPDUs transmitted by other stations on the medium. A Non-DMN Port shall be configured to only process the MSRPDUs transmitted by DMN Ports, and ignore the MSRPDUs transmitted by other Non-DMN Ports. Furthermore, the DMN has the absolute control of the resource allocation on the shared medium. Given these two facts, a DMN can effectively control which reservations are and are not successful on the medium it controls.

Annex C provides examples on various shared media.

35.1.2 Behavior of end stations

35.1.2.1 Talkers

To announce the Streams that can be supplied and their characteristics, Talkers use the MAD_Join.request primitive (10.2) to make the Talker Declarations (35.2.1.3). To indicate the Streams that are no longer supplied, Talkers use the MAD_Leave.request primitive (10.2) to withdraw their Talker Declarations.

The Talker shall issue an MVRP VLAN membership declaration prior to issuing the Talker Declaration. The MVRP VLAN membership shall contain the vlan_identifier of the DataFrameParameters [item b) in 35.2.2.8.3], so that the neighboring Bridge adds the associated Bridge Port to the member set for the VLAN.

NOTE—VLAN membership is needed for the Talker when the neighboring Bridge has the Enable Ingress Filtering parameter set (8.6.2).

Talker Declarations are propagated by MSRP such that the Listeners and Bridges are aware of the presence of Talkers and the Streams that are offered. Talker Declarations are also used to gather QoS information along their paths. Based on the gathered QoS information, Talker Declarations are classified as follows:

a) **Talker Advertise:** An advertisement for a Stream that has not encountered any bandwidth or other network constraints along the network path from the Talker. Listeners that request attachment to this Stream are likely to create a reservation with the described QoS. A Talker Advertise will continue to be declared as long as the resources continue to be available.
b) **Talker Failed:** An advertisement for a Stream that is not available to the Listener because of bandwidth constraints or other limitations somewhere along the path from the Talker.

A Talker Advertise shall not be declared if there are not sufficient bandwidth and resources available. If a Talker Advertise is being declared and the required bandwidth or resources become unavailable the Talker Advertise shall be withdrawn and a Talker Failed may be declared. A Talker is allowed to transition directly from a Talker Advertise to a Talker Failed without waiting for the Talker Advertise to be deregistered from the network (see 35.2.6).

Talkers respond to the registration and deregistration events of Listener Declarations (35.2.1.3), signaled by MAD as follows:

On receipt of a MAD_Join.indication for a Listener Declaration, the Talker first merges (35.2.4.4.3) the Listener Declarations that it has registered for the same Stream. Then the Talker examines the StreamID (35.2.2.8.2) and Declaration Type (35.2.1.3) of the merged Listener Declaration. If the merged Listener Declaration is associated with a Stream that the Talker can supply, and the DeclarationType is either Ready or Ready Failed (i.e., one or more Listeners can receive the Stream), the Talker can start the transmission for this Stream immediately. If the merged Listener Declaration is an Asking Failed, the Talker shall stop the transmission for the Stream, if it is transmitting.

On receipt of a MAD_Leave.indication for a Listener Declaration, if the StreamID of the Declaration matches a Stream that the Talker is transmitting, then the Talker shall stop the transmission for this Stream, if it is transmitting.

35.1.2.2 Listeners

To indicate what Streams they want to receive, Listeners use the MAD_Join.request primitive (10.2) to make the Listener Declarations (35.2.1.3). To indicate the Streams that are no longer wanted, Listeners use the MAD_Leave.request primitive (10.2) to withdraw their Listener Declarations.

The Listener Declaration also conveys the results of the bandwidth and resource allocation along its path back to the Talker. Based on those results, Listener declarations are classified as follows:

a) **Listener Ready:** One or more Listeners are requesting attachment to the Stream. There is sufficient bandwidth and resources available along the path(s) back to the Talker for all Listeners to receive the Stream.
b) **Listener Ready Failed:** Two or more Listeners are requesting attachment to the Stream. At least one of those Listeners has sufficient bandwidth and resources along the path to receive the Stream, but one or more other Listeners are unable to receive the stream because of network bandwidth or resource allocation problems.
c) **Listener Asking Failed:** One or more Listeners are requesting attachment to the Stream. None of those Listeners are able to receive the Stream because of network bandwidth or resource allocation problems.

NOTE 1—The reader will notice that the Talker response to Ready and Ready Failed declarations is the same: the Talker can begin transmitting the Stream. Talkers might choose to pass the Ready Failed response to a higher layer protocol that could notify the user that the Stream is flowing, but not all Listeners are receiving it. It would be the responsibility of that higher layer to respond to this information as appropriate.

If the Listener receives a Talker Advertise declaration, and the Listener is ready to receive the Stream, the Listener shall issue an MSRP Listener Ready declaration for the Stream.

The Listener shall issue an MVRP VLAN membership declaration prior to issuing the MSRP Listener Ready declaration. The MVRP VLAN membership shall contain the vlan_identifier of the Talker Advertise DataFrameParameters [item b) in 35.2.2.8.3], so that the neighboring Bridge adds the associated Bridge Port to the member set for the VLAN.

If the *talkerVlanPruning* parameter (35.2.4.3.4) is not enabled in the Bridges in the path from Talker to the Listener, the Listener receives Talker Advertise prior to declaring MVRP VLAN membership. The Listener can then use the registered Talker Advertise to obtain the vlan_identifier for declaration of MVRP VLAN membership. This is the default behavior for the *talkerVlanPruning* parameter.

If one or more Bridges in the path from Talker to the Listener have enabled the *talkerVlanPruning* parameter, the Listener declares VLAN membership prior to receiving the Talker Advertise declaration. The *talkerVlanPruning* parameter instructs the Bridge to filter Talker declarations for the VLAN (in addition to the VLAN-tagged data frames of the stream). If the *talkerVlanPruning* parameter is enabled and the VLAN is not Registration Fixed (8.8.10), the Listener obtains knowledge of the Talker's vlan_identifier from a higher layer protocol above IEEE Std 802.1Q and uses that knowledge to declare the membership for the vlan_identifier with MVRP.

If *talkerPruning* or *talkerPruningPerPort* is enabled, the Listener must issue an MMRP registration for the Stream's destination MAC address as described in 35.2.4.2 before the Talker Advertise will be received.

If the Listener receives a Talker Failed declaration, and the Listener is ready to receive the Stream, the Listener shall issue either an MSRP Listener Asking Failed declaration or an MSRP Listener Ready declaration for the Stream.

There is no requirement for the order in which the Talker and Listener declarations are communicated. The Listener Declaration can be made before the Listener receives an associated Talker Declaration, in which case the Listener shall issue a Listener Asking Failed declaration.

NOTE 2—One reason for the Listener to issue Listener Ready in response to Talker Failed is that the Listener wants to inform the network that it is ready to proceed in case the Talker's state changes from failed to ready in the future.

35.1.3 Behavior of Bridges

MSRP-aware Bridges register and deregister Talker and Listener declarations on the Bridge Ports according to the procedures defined in MRP (Clause 10), and automatically generate deregistration of stale registrations. Any changes in the state of registration are processed by the MSRP Attribute Propagation (35.2.4) function, and disseminated in the network by making or withdrawing Talker and Listener declarations as defined in the Talker attribute propagation (35.2.4.3) and Listener attribute propagation (35.2.4.4).

In general, Talker declarations are propagated to all other Bridge Ports. There are *talkerPruning* [item b) in 35.2.1.4], *talkerPruningPerPort* [item k) in 35.2.1.4], and *talkerVlanPruning* [item l) in 35.2.1.4] parameters that limit the scope of Talker declaration propagation. Listener declarations are only propagated to the Bridge Port with the associated Talker declaration (i.e., matching StreamID). If there is no associated Talker declaration registered on any Bridge Port then Listener declaration will not be propagated.

35.1.3.1 Blocked Declarations

For the purposes of MSRP Attribute Propagation (35.2.4), a Declaration is said to be "blocked" on a Bridge Port if the state of the spanning tree instance identified by the vlan_identifier in the DataFrameParameters (35.2.2.8.3) of the Declaration, on that Bridge Port, has any value other than Forwarding. In an end station's MSRP Participant, no Declaration is ever blocked.

35.1.4 SRP domains and status parameters

An SRP domain is a set of stations (end stations and/or Bridges), their Ports, and the attached individual LANs, that satisfy all of the following conditions for a given SR class:

a) Those stations that transmit streams all support the credit-based shaper algorithm, defined in 8.6.8, as the transmission selection method for the SR class.
b) The stations all support SRP as the means of creating bandwidth reservations for the SR class.
c) Those stations that transmit streams all associate the same priority value with the SR class.
d) Each Port in the set is either an SRP domain core port or an SRP domain boundary port.
e) Each SRP domain core Port in the set is connected, via an individual LAN that is part of the active topology, to an SRP domain core Port of another station in the set.

In Bridges that support the SRP, and for each SR class supported by the Bridge, an **SRPdomainBoundaryPort** parameter is associated with each Port of the Bridge.

Each SRPdomainBoundaryPort parameter has a Boolean value. The value of the SRPdomainBoundaryPort parameter for a given SR class is TRUE if the operation of SRP has determined that the Port is an SRP domain boundary port (3.260) for that SR class; otherwise, the Port either is an SRP domain core port (3.261) for that SR class or is not part of that SRP domain, and the SRPdomainBoundaryPort parameter value is FALSE.

35.2 Definition of the MSRP application

MSRP maintains two categories of variables. The first category is used internally by the application state machines. These are defined in detail in the subclauses that follow.

MSRP also defines another category of variables identified as MRP elements that are communicated in MSRPDUs between stations on a network. These protocol elements include the MRP frame addressing and other fields defined in the MRPDUs. The MSRP FirstValue fields, which are used to exchange the MSRP attributes, are also defined here.

35.2.1 Definition of internal state variables

The following variables and parameters are utilized by various state machines within MSRP:

a) Port Media Type (35.2.1.1);
b) Direction (35.2.1.2);
c) Declaration Type (35.2.1.3);
d) SRP parameters (35.2.1.4);

35.2.1.1 Port Media Type

MSRPDU processing on a port is handled differently depending on the type of medium the port is attached to. For example, the DMN on a shared medium port that receives MSRPDUs from one station shall update and retransmit those attributes so that all stations on that medium are updated appropriately. The possible values are as follows:

a) **Access Control Port:** Transmitter controls access to the medium on which it is sending, so either it is the DMN for a shared medium, or it is a port on a full-duplex point-to-point medium.
b) **Non-DMN shared medium Port:** Transmitter is attached to a shared medium, but does not control access to the medium.

35.2.1.2 Direction

The Direction field is derived from the MSRP AttributeType definitions (35.2.2.4). The Direction indicates whether this is a Talker: MSRP AttributeType definitions of type Talker Advertise Vector Attribute Type [item a) in 35.2.2.4], Talker Failed Vector Attribute Type [item b) in 35.2.2.4], or Talker Enhanced Vector Attribute Type [item e) in 35.2.2.4]. Set Direction to zero for Talker attributes. or a Listener MSRP Declaration, and takes one of the following two values:

a) **Talker:** MSRP AttributeType definitions of type Talker Advertise Vector Attribute Type [item a) in 35.2.2.4], Talker Failed Vector Attribute Type [item b) in 35.2.2.4], or Talker Enhanced Vector Attribute Type [item e) in 35.2.2.4]. Set Direction to zero for Talker attributes.
b) **Listener:** MSRP AttributeType definitions of type Listener Vector Attribute Type [item c) in 35.2.2.4] or Listener Enhanced Vector Attribute Type [item f) in 35.2.2.4]. Set Direction to one for Listener attributes.

35.2.1.3 Declaration Type

The Declaration Type field is derived from the MSRP AttributeType definitions (35.2.2.4) and the MSRP FourPackedEvents (35.2.2.7.2). The Declaration Type indicates the specific type of the Talker or Listener MSRP Declaration.

For a Talker, the value of the Declaration Type component is either:

a) **Advertise:** MSRP AttributeType definitions of Talker Advertise Vector Attribute Type [item a) in 35.2.2.4] or Talker Enhanced Vector Attribute Type [item e) in 35.2.2.4] with Status.StatusInfo.TalkerStatus equal to Ready (35.2.2.10.9). Set Declaration Type to zero for Talker Advertise.

b) **Failed:** MSRP AttributeType definitions of Talker Failed Vector Attribute Type [item b) in 35.2.2.4] or Talker Enhanced Vector Attribute Type [item e) in 35.2.2.4] with Status.StatusInfo.TalkerStatus equal to Failed (35.2.2.10.9). Set Declaration Type to one for Talker Failed.

For a Listener, the value of the Declaration Type component is one of the following:

c) **Asking Failed:** MSRP AttributeType definitions of Listener Vector Attribute Type [item c) in 35.2.2.4] with MSRP FourPackedType equal to Asking Failed [item b) in 35.2.2.7.2] or Listener Enhanced Vector Attribute Type [item f) in 35.2.2.4] with Status.StatusInfo.ListenerStatus equal to Failed (35.2.2.10.9). Set Declaration Type to two for Listener Asking Failed.

d) **Ready:** MSRP AttributeType definitions of Listener Vector Attribute Type with MSRP FourPackedType equal to Ready [item c) in (35.2.2.7.2] or Listener Enhanced Vector Attribute Type [item f) in 35.2.2.4] with Status.StatusInfo.ListenerStatus equal to Ready (35.2.2.10.9). Set Declaration Type to three for Listener Ready.

e) **Ready Failed:** MSRP AttributeType definitions of Listener Vector Attribute Type with MSRP FourPackedType equal to Ready Failed [item d) in 35.2.2.7.2] or Listener Enhanced Vector Attribute Type [item f) in 35.2.2.4]) with Status.StatusInfo.ListenerStatus equal to PartialFailed (35.2.2.10.9). Set Declaration Type to four for Listener Ready Failed.

35.2.1.4 SRP parameters

The following parameters are used by SRP:

a) **portTcMaxLatency**: The maximum per-port per-traffic class latency, expressed in nanoseconds, a frame may experience through the underlying MAC Service. There may be different latency numbers for different traffic classes on the same port.

b) ***talkerPruning***: Enabling this parameter on the Bridge will limit the Talker declarations to Ports that have the Streams destination_address [item a) in 35.2.2.8.3] in the MAC Address Registration Entries (8.8.4), such as by using MMRP.

c) ***streamAge***: A per-port per-stream 32-bit unsigned value used to represent the time, in seconds, since the control element for the associated port most recently became forwarding in the Dynamic Reservations Entries (8.8.7) corresponding to the stream's destination_address. This value is used when determining which streams have been configured the longest. Streams with a numerically larger streamAge are considered to be configured earlier than other streams and therefore carry a higher implicit importance.

NOTE 1—A 32-bit unsigned value allows for expressing a streamAge of up to 136 years.

d) **msrpEnabledStatus:** MSRP shall have the ability to be enabled (true) or disabled (false) on a device. When MSRP is enabled on a device it shall cause a reset of all MSRP state machines on all ports. This affects the Applicant and Registrar state machines. The state of this parameter shall be persistent over power-up restart/reboot.

e) **msrpPortEnabledStatus:** MSRP shall have the ability to be enabled (true) or disabled (false) on the ports of a device. When MSRP is enabled or disabled on a port of a device it shall cause MAP to be rerun on all MSRP enabled ports so existing attributes can be propagated to the port just enabled. This affects the Applicant and Registrar state machines. The state of this parameter shall be persistent over power-up restart/reboot.

f) **msrpMaxFanInPorts:** The total number of ports on a Bridge that are allowed to establish reservations for inbound Streams. This number may be less than the total number of ports with msrpPortEnabledStatus set TRUE, which will result in lower maximum latency because of limits on the amount of possible interfering traffic. A value of zero (0) indicates no fan-in limit is being specified and calculations involving fan-in will only be limited by the number of MSRP enabled ports. Example calculations of delay associated with fan-in can be found in the paper "Calculating the Delay Added by Qav Stream Queue" [B3].

g) **msrpLatencyMaxFrameSize:** Calculation of the maximum latency through a Bridge is in-part related to the maximum size of an interfering frame. The maximum size is defined to be 2000 octets by default. This parameter allows a smaller or larger value to be used in the latency calculations for the particular Bridge implementation. msrpLatencyMaxFrameSize does not imply any type of policing of frame size, it is only used in the latency calculations.

h) **SRPdomainBoundaryPort (35.1.4)**: A per-port, per-SR class, Boolean parameter that contains the value TRUE if the port is an SRP Domain Boundary Port; otherwise, it contains the value FALSE. The parameter for a given SR class and Port shall be set to TRUE if any of the following conditions are met:

1) The port is declaring an MSRP Domain attribute for that SR class, and the port has no MSRP Domain attribute registrations for that SR class, or
2) The port is declaring an MSRP Domain attribute for that SR class, and the port has at least one MSRP Domain attribute registration for that SR class with a different priority, or
3) One or more ports which support that SR class are declaring MSRP Domain attributes for that SR class, and this port does not support that SR class.

In all other cases the parameter shall be set to FALSE.

i) **SR_PVID:** The Stream Reservation Port VLAN Identifier is a per-port parameter that contains the default VID for Stream-related traffic. It shall contain a valid VID value (Table 9-2) and may be configured by management. If the value has not been explicitly configured, the SR_PVID shall assume the default SR_PVID defined in Table 9-2. This value is passed to the Talker via the SRclassVID (35.2.2.9.4) contained in the MSRP Domain attribute.

j) ***neighborProtocolVersion:*** Each Port provides a neighborProtocolVersion parameter that specifies the MSRP ProtocolVersion of the neighboring MSRP Participant on that Port. The initial value is 0x00. When an MSRP Domain attribute is registered (received) on the Port, the value of the attribute's MRP ProtocolVersion (35.2.2.1) is copied to this parameter.

k) ***talkerPruningPerPort:*** When the talkerPruning parameter is disabled (false), each Port provides a talkerPruningPerPort parameter to control MAC address pruning for that Port. For more information, refer to 35.2.4.3.3.

l) ***talkerVlanPruning:*** Enabling this parameter on the Bridge will limit the Talker declarations to Ports that have the Stream's vlan_identifier [item b) in 35.2.2.8.3] registered as a member in the VLAN Registration Entries (8.8). For more information, refer to 35.2.4.3.4.

m) ***maxSRclasses:*** This parameter provides the maximum number of SR classes supported by the Bridge.

35.2.2 Definition of MRP elements

35.2.2.1 MSRP application address

The group MAC address used as the destination address for MRPDUs destined for MSRP Participants shall be the group MAC address for "Individual LAN Scope group address, Nearest Bridge group address" as specified in Table 8-1, Table 8-2, and Table 8-3 (C-VLAN, S-VLAN, and TPMR component Reserved addresses, respectively).

NOTE—Using this address will guarantee that MSRPDUs are never forwarded by an 802.1 Bridge, although MSRP-aware Bridges do propagate the MSRP attributes.

35.2.2.2 MSRP application EtherType

The EtherType used for MRPDUs destined for MSRP Participants shall be the MSRP EtherType identified in Table 10-2.

35.2.2.3 MSRP ProtocolVersion

The ProtocolVersion for the version of MSRP defined in this standard takes the hexadecimal value 0x01.

NOTE—Although an MSRP Participant for this standard transmits MSRPDUs using ProtocolVersion 0x01, the MSRP Participant must process received MSRPDUs using ProtocolVersion 0x01 or 0x00, as specified in 10.8.3.5.

35.2.2.4 MSRP AttributeType definitions

MSRP defines six AttributeTypes (10.8.2.2) that are carried in MRP exchanges. The numeric values for the AttributeType are shown in Table 35-1 and their use is defined by the following list:

a) **Talker Advertise Vector Attribute Type:** Attributes identified by the Talker Advertise Vector Attribute Type are instances of VectorAttributes (10.8.1), used to identify a sequence of values of Talker advertisements for related Streams that have not been constrained by insufficient bandwidth or resources. This Attribute Type applies to all versions of MSRP.

b) **Talker Failed Vector Attribute Type:** Attributes identified by the Talker Failed Vector Attribute Type are instances of VectorAttributes, used to identify a sequence of values of Talker advertisements for related Streams that have been constrained by insufficient bandwidth or resources.This Attribute Type applies to all versions of MSRP.

c) **Listener Vector Attribute Type:** Attributes identified by the Listener Vector Attribute Type are instances of VectorAttributes, used to identify a sequence of values of Listener requests for related Streams regardless of bandwidth constraints. Listener Vector Attribute Types are subdivided into individual Declaration Types via the MSRP FourPackedEvents (35.2.2.7.2).This Attribute Type applies to all versions of MSRP.

d) **Domain Vector Attribute Type:** Attributes identified by the Domain Vector Attribute Type are instances of VectorAttributes, used to identify a sequence of values that describe the characteristics of an SR class. This Attribute Type applies to all versions of MSRP.

e) **Talker Enhanced Vector Attribute Type:** Attributes identified by the Talker Enhanced Vector Attribute Type are instances of VectorAttributes (10.8.1), used to identify a sequence of values of Talker advertisements for related Streams. Talker Enhanced Vector Attribute Types are subdivided into individual Declaration Types (35.2.1.3) via the Status.StatusInfo.TalkerStatus (35.2.2.10.9). This Attribute Type applies to ProtocolVersion 0x01 or higher.

f) **Listener Enhanced Vector Attribute Type:** Attributes identified by the Listener Enhanced Vector Attribute Type are instances of VectorAttributes, used to identify a sequence of values of Listener requests for related Streams. Listener Enhanced Vector Attribute Types are subdivided into individual Declaration Types (35.2.1.3) via the Status.StatusInfo.ListenerStatus (35.2.2.10.9). This Attribute Type applies to ProtocolVersion 0x01 or higher.

35.2.2.5 MSRP AttributeLength definitions

The AttributeLength field (10.12.1.8) in instances of the Talker Advertise Vector Attribute Type shall be encoded in MRPDUs (10.8) as an unsigned binary number, equal to the value shown in Table 35-2.

The AttributeLength field in instances of the Talker Failed Vector Attribute Type shall be encoded in MRPDUs as an unsigned binary number, equal to the value shown in Table 35-2.

The AttributeLength field in instances of the Listener Vector Attribute Type shall be encoded in MRPDUs as an unsigned binary number, equal to the value shown in Table 35-2.

Table 35-1—AttributeType Values

AttributeType	Value	Used when neighborProtocolVersion is 0x00	Used when neighborProtocolVersion is 0x01 or higher
Talker Advertise Vector	1	yes	yes
Talker Failed Vector	2	yes	yes
Listener Vector	3	yes	yes
Domain Vector	4	yes	yes
Talker Enhanced Vector	5	no	yes
Listener Enhanced Vector	6	no	yes

Table 35-2—AttributeLength Values

AttributeType	Value
Talker Advertise Vector	25 (0x19)
Talker Failed Vector	34 (0x22)
Listener Vector	8
Domain Vector	4
Talker Enhanced Vector	variable
Listener Enhanced Vector	variable

The AttributeLength field in instances of the Domain Vector Attribute Type shall be encoded in MRPDUs as an unsigned binary number, equal to the value shown in Table 35-2.

The AttributeLength field in instances of the Talker Enhanced Vector Attribute Type and Listener Enhanced Vector Attribute Type shall be encoded in MRPDUs as an unsigned binary number. The value of AttributeLength varies according to the TLVs contained in the attribute's value, but shall not change during the duration of the attribute's declaration.

35.2.2.6 MSRP AttributeListLength definitions

The AttributeListLength field (10.12.1.9) shall be encoded in MRPDUs (10.8) as an unsigned binary number, equal to the number of octets contained within the AttributeList. This field can be used when calculating the number of octets to skip to proceed to the next Message (or Message EndMark) in the MRPDU.

35.2.2.7 MSRP Vector definitions

35.2.2.7.1 MSRP ThreePackedEvents

The ThreePackedEvent vectors are encoded as defined in 10.8.2.10.1.

35.2.2.7.2 MSRP FourPackedEvents

MSRP FourPackedEvents are only used by the Listener Vector Attribute Type [item c) in 35.2.2.4]. Within the FourPackedEvent, there are four possible values for the FourPackedType (10.8.2.10.2) as explained in the following list. The numeric values for the MSRP FourPackedEvents are shown in Table 35-3.

a) **Ignore:** The StreamID referenced by FirstValue+n is not defined in this MSRPDU. When using this FourPackedType, the AttributeEvent (10.8.2.10.1) value, encoded in the ThreePackedEvent, shall be set to zero on transmit and ignored on receive.
b) **Asking Failed:** The StreamID referenced by FirstValue+n has a declaration type of Listener Asking Failed.
c) **Ready:** The StreamID referenced by FirstValue+n has a declaration type of Listener Ready.
d) **Ready Failed:** The StreamID referenced by FirstValue+n has a declaration of type Listener Ready Failed.

Table 35-3—FourPackedEvent Values

FourPackedType	Value
Ignore	0
Asking Failed	1
Ready	2
Ready Failed	3

NOTE 1—In terms of efficient use of octets within an MSRP packet, placing nineteen (19) Ignores between two Listener declarations uses less octets than using two VectorAttributes to declare the Listener attributes separately. A single Listener VectorAttribute takes 12 octets, two attributes would take 24 octets. Declaring 21 attributes (two valid attributes with 19 Ignores in between) takes 12 octets, plus 6 additional ThreePackedEvents, plus 5 additional FourPackedEvents for a total of 23 octets.

NOTE 2—MSRP FourPackedEvents are not used for the Listener Enhanced Vector Attribute Type [item f) in 35.2.2.4], which uses the Status.StatusInfo.ListenerStatus (35.2.2.10.9) to distinguish Declaration Types (35.2.1.3).

35.2.2.8 MSRP FirstValue definitions (Stream reservations, original)

There are four Attribute Declarations defined for the original ProtocolVersion 0x00 of MSRP (35.2.2.4), three of which are related to stream reservations: Talker Advertise, Talker Failed, and Listener. The fourth attribute type, Domain, is used to discover the SRP domain, as well as the ProtocolVersion of each Port's neighbor, and is described in 35.2.2.9.

NOTE—This version of MSRP requires implementation of the original attributes of 35.2.2.8 and the enhanced attributes of 35.2.2.10. The specifications for enhanced attributes are based on the specifications for original attributes.

The Talker Advertise attribute contains all the characteristics that a Bridge needs in order to understand the resource requirements and importance of the referenced stream.

The Talker Failed attribute contains all the fields carried in the Talker Advertise Attribute, plus additional information regarding resource or bandwidth availability failures.

Listener attributes carry three subtypes: Ready, Ready Failed, and Asking Failed. These Listener subtypes are encoded in the FourPackedEvent (35.2.2.7.2).

FirstValue shall be incremented one or more times when NumberOfValues is greater than one. Incrementing FirstValue within MSRP is defined as follows:

a) Add 1 to Unique ID [item b) in 35.2.2.8.2], and
b) Add 1 to Stream destination_address [item a) in 35.2.2.8.3].

The example shown in Table 35-4 illustrates the use of FirstValue and NumberOfValues within MSRP. This example shows four Streams (a, b, c, and d) to be declared. In order to use the efficient packing techniques of MRP it would be preferable to assign these Streams sequential StreamIDs and destination_addresses as shown. Notice that StreamID yy-yy-yy-yy-yy-yy:00-04 is missing from this table (between Stream "c" and "d"). MSRP allows declaration of all four StreamIDs in a single VectorAttribute by setting NumberOfValues=5, with the StreamID = yy-yy-yy-yy-yy-yy:00-01 and a destination_address of xx-xx-xx-xx-xx-25. Setting the fourth FourPackedEvent to Ignore [item a) in 35.2.2.7.2] notifies MSRP that the StreamID between "c" and "d" is not in use.

Table 35-4—MSRP FirstValue NumberOfValues example

Stream	StreamID	destination_address
a	yy-yy-yy-yy-yy-yy:00-01	xx-xx-xx-xx-xx-25
b	yy-yy-yy-yy-yy-yy:00-02	xx-xx-xx-xx-xx-26
c	yy-yy-yy-yy-yy-yy:00-03	xx-xx-xx-xx-xx-27
d	yy-yy-yy-yy-yy-yy:00-05	xx-xx-xx-xx-xx-29

The FirstValue field within MSRP comprises several components: StreamID (35.2.2.8.2), DataFrameParameters (35.2.2.8.3), TSpec (35.2.2.8.4), PriorityAndRank (35.2.2.8.5), Accumulated Latency (35.2.2.8.6), and FailureInformation (35.2.2.8.7). MSRP does not support changes in any of the FirstValue fields for an existing StreamID. If a Talker wishes to tear an old Stream down and bring a new Stream up, with a different FirstValue, utilizing the same StreamID, there must be at least two LeaveAllTime (Table 10-7) time periods between when the Talker removes the existing Stream registration and declares the new Stream. This guarantees that MRP has enough time to remove the current attribute from all devices in the network. If the new declaration were to occur too quickly the associated Streaming data could be corrupted because the FDB may allow the new Stream data to start flowing while the old Stream bandwidth constraints are still configured. When the Bridge detects this occurring it will fail the Talker Advertise with the appropriate FailureInformation (35.2.2.8.7). Talkers may tear a Stream down and bring the same Stream back up immediately, as long as the FirstValue has not changed.

35.2.2.8.1 Structure definition

The FirstValue for Talker Advertise, Talker Failed, and Listener attributes in MSRPDUs exchanged according to the protocol specified in this subclause shall have the following structure:

a) The first eight octets contain the *StreamID* (35.2.2.8.2).

   This is the end of the Listener attribute. If this is a Talker Advertise or Talker Failed attribute continue as follows:

b) Following the StreamID are eight octets containing the *DataFrameParameters* (35.2.2.8.3).
c) Following the DataFrameParameters are four octets containing the *TSpec* (35.2.2.8.4).
d) Following the TSpec is one octet containing the *PriorityAndRank* (35.2.2.8.5).
e) Following the PriorityAndRank are four octets containing the *AccumulatedLatency* (35.2.2.8.6).

   This is the end of the Talker Advertise attribute. If this is a Talker Failed attribute continue as follows:

f) Following the AccumulatedLatency are nine octets containing the *FailureInformation* (35.2.2.8.7).

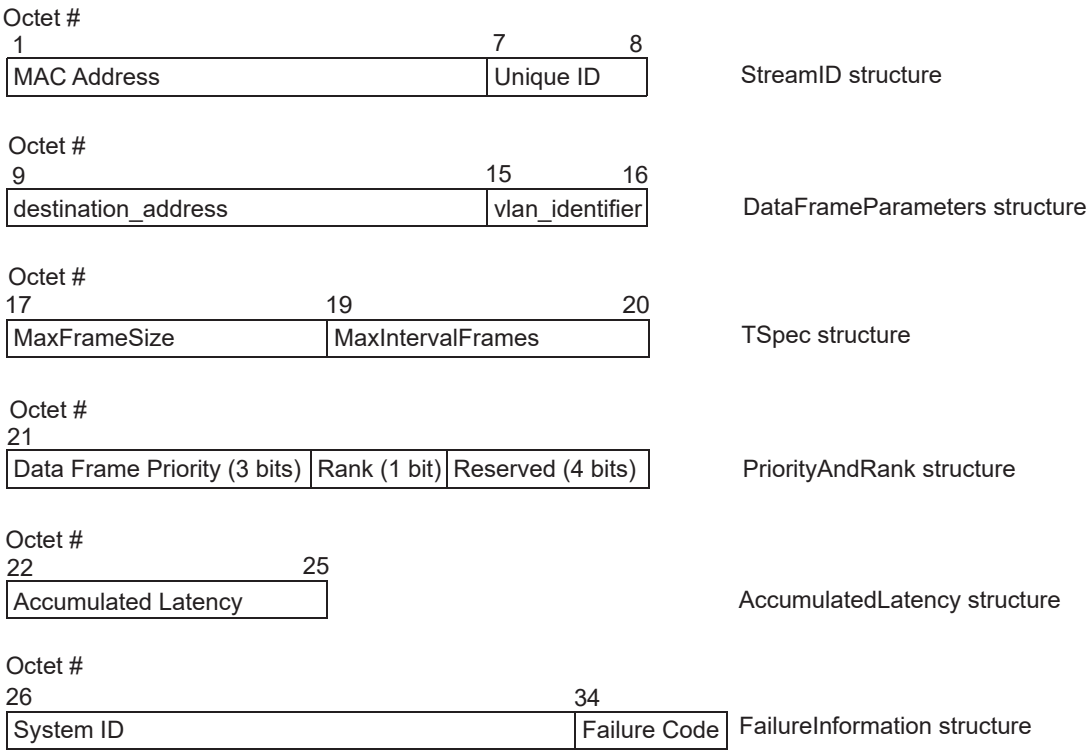

Figure 35-2—Format of the components of the reservation FirstValue fields

The following partial BNF production gives the formal description of the MSRPDU FirstValue structure for the Talker Advertise attribute:

FirstValue ::= StreamID, DataFrameParameters, TSpec, PriorityAndRank, AccumulatedLatency

The following partial BNF production gives the formal description of the MSRPDU FirstValue structure for the Talker Failed attribute:

FirstValue ::= StreamID, DataFrameParameters, TSpec, PriorityAndRank, AccumulatedLatency, FailureInformation

The following partial BNF production gives the formal description of the MSRPDU FirstValue structure for the Listener attribute:

FirstValue ::= StreamID

Figure 35-2 illustrates the structure of the MSRPDU FirstValue components. Each MSRP Attribute shall only use those structures as defined by the partial BNF productions described previously. The octet numbers shown represent the octet location within the FirstValue field.

35.2.2.8.2 StreamID

The 64-bit StreamID is used to match Talker registrations with their corresponding Listener registrations (35.2.4). The StreamID comprises the following two subcomponents:

a) A 48-bit MAC Address associated with the Talker sourcing the stream to the bridged network. The entire range of MAC addresses are acceptable.
b) A 16-bit unsigned integer value, Unique ID, used to distinguish among multiple streams sourced by the same Talker.

StreamIDs are unique across the entire bridged network and are generated by the system offering the stream, or possibly a device controlling that system. A system reserving resources for more than one stream in the same bridged network shall use a StreamID that is unique among all StreamIDs in that bridged network. The combination of these two subcomponents ensure that such an assignment is possible.

NOTE 1—The spanning tree protocol ensures that there can be at most one path from a Talker to its Listener(s). Multiple Declarations for the same StreamID can therefore occur briefly, during changes in the active topology of the bridged network.

NOTE 2—The MAC address component of the StreamID can, but does not necessarily, have the same value as the source_address parameter of any frame in the actual data stream. For example, the StreamID can be assigned by a TSN CUC (see 46.1.3.3), using a pool of MAC addresses that the TSN CUC maintains.

NOTE 3—If the MAC addresses used to construct StreamIDs are not unique within the network, duplicate StreamIDs can be generated, with unpredictable results for SRP.

35.2.2.8.3 DataFrameParameters

The DataFrameParameters component of the MSRP Attribute specifies the EISS parameters that are common to all frames belonging to the data stream for which this MAD is reserving resources. This information is used by Bridges to create Dynamic Reservation Entries (8.8.7). The parameters are as follows:

a) The destination_address
b) The vlan_identifier

The destination_address specifies the destination MAC address of the streaming data frames. Only one Stream is allowed per destination_address. MSRP does not describe the actual streaming data, only the bandwidth associated with that stream.

The use of destination_address for both a Stream and “best effort” traffic (34.5) is outside the scope of SRP. SRP only supports destination_addresses that are multicast or locally administered addresses.

NOTE—MSRP enforces reserved bandwidth guarantees by filtering Stream destination addresses (35.2.4.4.2) for Streams that do not have a reservation. This blocks all traffic to that destination address. If that destination address was also being used for “best effort” traffic that device would no longer be reachable.

Systems that are not VLAN aware shall use the value SRclassVID (35.2.2.9.4) for the vlan_identifier in the DataFrameParameters. VLAN-aware systems may use any valid VID (1 through 4094).

35.2.2.8.4 TSpec

The 32-bit TSpec component is the TSpec associated with a Stream. It consists of the following two elements (which are encoded as described in 10.8.1.1):

a) **MaxFrameSize:** The 16-bit unsigned MaxFrameSize component is used to allocate resources and adjust queue selection parameters in order to supply the QoS requested by an MSRP Talker Declaration. It represents the maximum frame size that the Talker will produce, excluding any overhead for media-specific framing (e.g., preamble, IEEE 802.3 header, Priority/VID tag, CRC, interframe gap). As the Talker or Bridge determines the amount of bandwidth to reserve on the egress port it will calculate the media-specific framing overhead on that port and add it to the number specified in the MaxFrameSize field.
b) **MaxIntervalFrames:** The 16-bit unsigned MaxIntervalFrames component is used to allocate resources and adjust queue selection parameters in order to supply the QoS requested by an MSRP Talker Declaration. It represents the maximum number of frames that the Talker may transmit in one classMeasurementInterval (34.3).

NOTE—Consider the example of a Class A 48kHz stereo audio stream encapsulated in an Ethernet frame (see IEEE Std 1722™ [B16]). The audio data within the frame would contain two sets of six 32-bit samples, plus a 32-octet header, for a total of 80 octets per frame sent once every class measurement interval (34.4). Therefore, MaxFrameSize=80, and MaxIntervalFrames=1. An IEEE 802.3 port on a Bridge would also add 42 octets of media-

specific framing overhead (8-octet preamble, 14-octet IEEE 802.3 header, 4-octet IEEE 802.1Q priority/VID Tag, 4-octet CRC, 12-octet IFG). When the Bridge calculates the amount of bandwidth to reserve it would combine 42 octets of media-specific framing overhead with the MaxFrameSize of 80 octets, to arrive at a total frame size of 122 octets per class measurement interval. This represents a total bandwidth of approximately 7.7 Mb/s (122 octets × 8 b/octet × 8000 frames/s).

Table 35-5 contains some examples of various forms of audio and video Streams with their associated TSpec components.

Table 35-5—TSpec components examples

Source	Raw bit rate	Media-specific framing overhead	TSpec MaxFrameSize	TSpec MaxIntervalFrames
48kHz stereo audio stream (32-bit samples) Class A (IEEE Std 1722 [B16])	~3 Mb/s	~4.7 Mb/s	80	1 (8 000 frames/s)
96kHz stereo audio stream (32-bit samples) Class A (IEEE Std 1722 [B16])	~6 Mb/s	~4.7 Mb/s	128	1 (8 000 frames/s)
MPEG2-TS video Class B (IEEE Std 1722 [B16])	~24 Mb/s	~2.5 Mb/s	786	1 (4 000 frames/s)[a]
SD SDI (Level C) uncompressed Class A (SMPTE 259M-2008 [B60])	270 Mb/s	~15 Mb/s	1442	3 (24 000 frames/s)
SD SDI (Level D) uncompressed Class A (SMPTE 259M-2008 [B60])	360 Mb/s	~20 Mb/s	1442	4 (32 000 frames/s)
HD SDI 1080i uncompressed Class A (SMPTE 292M-2008 [B61])	1.485 Gb/s	~80 Mb/s	1486	16 (128 000 frames/s)
HD SDI 1080p uncompressed Class A (SMPTE 424M-2008 [B62])	2.97 Gb/s	~160 Mb/s	1486	32 (256 000 frames/s)

[a] The MPEG-2 TS entry in this table (third row) is shown as Class B traffic, which runs at a default frame rate of 250 μs/frame or 4000 frames/s. Class A traffic runs at a default rate of 8000 frames/s.

35.2.2.8.5 PriorityAndRank

a) **Data Frame Priority:** The 3-bit Data Frame Priority component specifies the priority value used to generate the Priority Code Point the referenced data streams will be tagged with. It indicates the priority EISS or ISS parameter that will be used in all frames belonging to the data stream for which this MAD is reserving resources. This parameter determines which queue the frame is placed into on an output Bridge Port. In accordance with 10.8.1.1 these three bits are in the most significant positions (8, 7, and 6). The priority specified here is associated with the SR Classes as described in 34.5.

b) **Rank:** The single-bit Rank component is used by systems to decide which streams can and cannot be served, when the MSRP registrations exceed the capacity of a Port to carry the corresponding data streams. If a Bridge becomes oversubscribed (e.g., network reconfiguration, IEEE 802.11 bandwidth reduction), the Rank will also be used to help determine which Stream or Streams can be dropped. A lower numeric value is more important than a higher numeric value. In accordance with 10.8.1.1 this bit is in position 5.

   For streams that carry emergency data such as North America 911 emergency services telephone calls, or fire safety announcements, the Rank shall be 0. Nonemergency traffic shall set this bit to a 1.

   NOTE—It is expected that higher layer applications and protocols can use the Rank to indicate the relative importance of streams based on user preferences expressed by means beyond the scope of this standard. The values and defaults provided by this Standard are sufficient to order streams on a first-come-first-served basis, with special priority provided for emergency services.

c) **Reserved:** This 4-bit field shall be zero filled on transmit and ignored on receive. In accordance with 10.8.1.1 these four bits are in the least significant positions (4, 3, 2, and 1).

35.2.2.8.6 Accumulated Latency

The 32-bit unsigned Accumulated Latency component is used to determine the worst-case latency that a Stream can encounter in its path from the Talker to a given Listener. The latency reported here is not intended to increase during the life of the reservation. If some event occurs that would increase the latency beyond the original guarantee, MSRP will change the Talker Advertise to a Talker Failed and report Failure Code=7 (Table 35-6).

NOTE 1—An example of how latency could increase is if the speed of the underlying media where to decrease, such as one might see on a wireless link.

The initial value sent by the Talker is set to *portTcMaxLatency* plus any amounts specified in the REGISTER_STREAM.request, and its value is increased by each Bridge as the Talker Declaration propagates through the network.

The *portTcMaxLatency* per hop is equal to the sum of the following:

a) (equal or higher priority traffic) the time required to empty the queue in which frames of that priority are placed, if that queue and all higher priority queues are full.
b) (lower priority traffic) the time required to transfer one lower priority frame of maximum size that could have just started transmitting as the current priority frame was queued up.
c) (internal processing) the worst-case time required by the Bridge to transfer a received frame from the input port to the output queue.
d) (wire propagation time) the time required for the first bit of the frame to propagate from the output port to the receiving device.
e) (media access delay) the time required to wait for the media to become available for transmission.

For item a) the total number of ports with msrpPortEnabledStatus set TRUE, and the msrpMaxFanInPorts will effect these calculations.[48]

For item a) and item b) the maximum size of the interfering traffic is limited to msrpLatencyMaxFrameSize octets.

For item d), the propagation time, if the managed object for Propagation Delay (12.32.2) is supported, txPropagationDelay shall be used. Otherwise, in the absence of better information, a value of 500 ns shall be used.

NOTE 2—This implies that no type of frame flow control can be used on the associated data stream frames.

The Listener can use this information to decide if the Latency is too large for acceptable presentation of the stream. The Accumulated Latency component is in units of nanoseconds.

35.2.2.8.7 FailureInformation

At the point when a Talker Advertise Declaration is transformed into a Talker Failed Declaration, the system making the transformation adds information that indicates, to the Listeners registering the Talker Failed Declaration, the cause of the failure and the identity of the system at which the failure occurred. The subcomponents of the FailureInformation include:

a) The system identifier, which is the Bridge Identifier (13.26.2) of the Bridge or the 48-bit MAC Address of the end station's port extended to 64-bits by prepending 16 bits of zero, that changed the Declaration Type from Advertise to Failed.

NOTE 1—Bridge Identifiers are normally constructed from MAC Addresses that are unique in the bridged LAN but are not required to be constructed in that manner; therefore, there is a possibility of an end station MAC Address colliding with the Bridge ID.

b) The Failure Code, which is represented by a single octet containing the value shown in Table 46-15.

NOTE 2—Although the table of failure codes (Table 46-15) is located in a subclause associated with MSRPv1, the codes are compatible with MSRPv0.

35.2.2.9 MSRP FirstValue definitions (Domain discovery)

The Domain attribute contains all the information that a Bridge Port needs in order to determine the location of the SRP domain boundary [item h) in 35.2.1.4]. The Domain attribute is also used to detect the ProtocolVersion of the neighboring MSRP Participant on each Bridge Port [item j) in 35.2.1.4].

The MSRP Participant shall declare (transmit) its Domain attribute after MAC_Operational (IEEE Std 802.1AC) transitions to TRUE and prior to declaring a Talker Advertise, Talker Failed, or Listener attribute.

FirstValue shall be incremented one or more times when NumberOfValues is greater than one. Incrementing FirstValue for the MSRP Domain attribute is defined as follows:

a) Add 1 to SRclassID (35.2.2.9.2), and
b) Add 1 to SRclassPriority (35.2.2.9.3).

The choice of encoding and incrementing with this rule means that if one class (e.g., class B) is supported, with the default values, then the FirstValue will be {5,2,VID} (class B, priority 2, and a VID) and the NumberOfValues field will be set to 1. If class A and class B are supported, with the default values, the FirstValue will again be {5,2,VID}, but the NumberOfValues fields will be set to 2. Applying the above incrementing rule to {5,2,VID} generates the value {6,3,VID}, i.e., class A, priority 3, and a VID, which is needed for the default case.

NOTE—If the SR Class to Priority Mapping Table (12.20.4) is configured through management such that SR class ID values do not increment contiguously with priority values, the declared domains need to be encoded in multiple Domain Vector Attributes. For example, if the SR class ID and priority rows are {2,4}, {3,0}, {4,1}, {5,2}, and {6,3}, two Domain attributes are needed: one Domain with FirstValue {2,4,VID} and NumberOfValues one, and a second Domain with FirstValue {3,0,VID} and NumberOfValues four.

[48] Example calculations for latency are contained in the paper "Calculating the Delay Added by Qav Stream Queue" [B3].

35.2.2.9.1 Structure definition

The FirstValue for the Domain attribute in MSRPDUs exchanged according to the protocol specified in this subclause shall have the following structure:

a) The first octet contains the *SRclassID* (35.2.2.9.2).
b) Following the SRclassID is an octet containing the *SRclassPriority* (35.2.2.9.3).
c) Following the SRclassPriority are two octets containing the *SRclassVID* (35.2.2.9.4).

The following BNF production gives the formal description of the MSRPDU FirstValue structure for the Domain attribute:

FirstValue ::= SRclassID, SRclassPriority, SRclassVID

Figure 35-3 illustrates the structure of the MSRPDU FirstValue components for the Domain attribute.

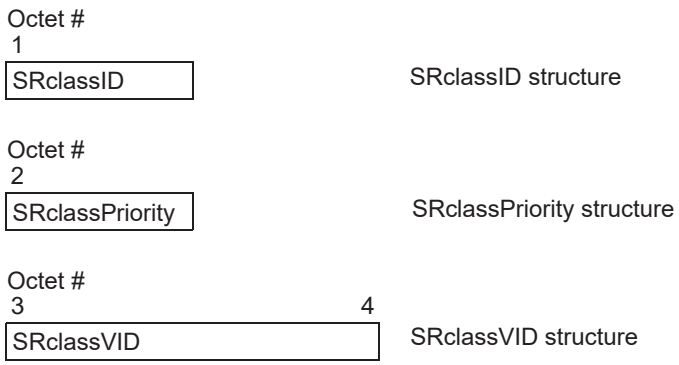

Figure 35-3—Format of the components of the Domain FirstValue

35.2.2.9.2 SRclassID

SRclassID is a numeric representation of the SR classes that are supported by a particular Bridge Port. The mapping of SR class letter to SR class ID is shown in Table 35-6.

Table 35-6—SR class ID

SR class	SR class ID
A	6
B	5
C	4
D	3
E	2
F	1
G	0

NOTE—When SRP is supported, only one SR class is required. Only SR classes A and B can be enabled by default. Additional SR classes must be configured through use of management (12.20.4, 34.5).

35.2.2.9.3 SRclassPriority

This fields holds the Data Frame Priority [item a) in 35.2.2.8.5] value that will be used for streams that belong to the associated SR class. Whenever an end station's MAC_Operational (IEEE Std 802.1AC) transitions to TRUE, its SRclassPriority shall be set to the default SR class priority (Table 6-5) until an SRclassPriority declaration is received from a neighboring device, at which time it shall be set to the declared value. An end station cannot change its default mapping of SR class to priority (see 12.20.4).

NOTE—This allows two end stations that are connected back-to-back to share streams, while also providing an end station the flexibility to change to the SRclassPriority of a attached network (i.e., neighboring Bridge).

35.2.2.9.4 SRclassVID

This field contains the SR_PVID [item i) in 35.2.1.4] that the associated streams will be tagged with by the Talker. Whenever an end station's MAC_Operational (IEEE Std 802.1AC) transitions to TRUE, its SRclassVID shall be set to the default SR_PVID (Table 9-2) until an SRclassVID declaration is received from a neighboring device, at which time it shall be set to the declared value.

NOTE—This allows two end stations that are connected back-to-back to share streams, while also providing an end station the flexibility to change to the SRclassVID of a attached network.

35.2.2.10 MSRP FirstValue definitions (Stream reservations, enhanced)

This subclause specifies two Attribute Types for enhanced stream reservations: Talker Enhanced and Listener Enhanced.

The specifications of the enhanced Attribute Types (35.2.2.10) are based on the specifications of the original Attribute Types (35.2.2.8), with differences stated explicitly.

As compared to the original Attribute Types, the enhanced Attribute Types use a Type-Length-Value (TLV) encoding for MSRP FirstValue. MSRP FirstValue contains a list of TLVs. Each TLV consists of a Type field that specifies what the Value field contains, a Length field that specifies the number of octets in the Value field, and the Value field. The Value contains one or more elements encoded in binary. The TLV encoding enables flexibility in the structure of MSRP FirstValue, such as support for optional features.

This subclause specifies the structure of MSRP FirstValue as well as the Type and Length for each TLV. This subclause also specifies the binary encoding of the elements within the Value of each TLV. The semantic specification of each element in the TLV's Value is provided as a reference to the corresponding group of elements in TSN User/network configuration information (46.2).

The transmission of octets in MSRP FirstValue is specified in 10.8.1.1. The encoding of the Value of each TLV is specified in a figure, and the representation in the figure is specified in 10.8.1.1. Elements marked as "reserved" shall be transmitted as zero and ignored on reception. When an element is not a multiple of 8 bits in length, the element is organized from most significant bit of the octet to least significant bit. Boolean elements are a single bit. When an element's Length in the figure is a decimal number only, Length specifies the number of octets for the element. When an element's Length in the figure is a decimal number followed by "bits," Length specifies the number of bits for the element.

FirstValue shall be incremented one or more times when NumberOfValues is greater than one, as follows:

a) Add 1 to Unique ID of the StreamID TLV (46.2.3.1), and
b) Add 1 to each element of the DataFrameSpecification TLV (46.2.3.4) that identifies the Stream:
    1) If the IEEE802-MacAddresses TLV is used, add 1 to DestinationMacAddress.
    2) If the IPv4-tuple TLV is used, add 1 to DestinationIpAddress.
    3) If the IPv6-tuple TLV is used, add 1 to DestinationIpAddress.

This rule for incrementing FirstValue is the same as the original Attribute Types (35.2.2.8), with the addition of optional support for IP destination address as the unique identification of the Stream.

NOTE 1—For an example of incrementing FirstValue for DestinationMacAddress, refer to 35.2.2.8.

NOTE 2—As compared to the fixed attribute values of the original AttributeTypes, the use of TLVs in the enhanced AttributeTypes allows each attribute value to vary based on the use of sub-TLVs. This imposes an additional constraint when NumberOfValues is greater than one such that all FirstValues must use the same sub-TLVs.

NOTE 3—As specified in 35.2.3.1, when a Talker or Listener has a *neighborProtocolVersion* of 0x00 (i.e., Nearest Bridge is MSRPv0), declarations must use only the original Attribute Types (35.2.2.8). If the application of the Talker/Listener is using the enhanced features of this subclause (35.2.2.10), an internal translation is needed in order to determine if the original Attribute Type can be declared. This internal translation is similar to the translation specified for MAP in a Bridge (Table 35-11 and Table 35-16), but it is outside the scope of this standard. If the enhanced features do not translate successfully to an original Attribute Type, the Talker or Listener can choose to either a) declare the failure to the network using an original Attribute Type (e.g., Talker Failed Vector of Table 35-1) or b) return an error up to the application of the Talker/Listener.

Some of the enhanced features of this subclause require the assistance of a Centralized Network Configuration (CNC) entity. As described in the introduction to Clause 35, in order to use a CNC with SRP, the MRP External Control (12.32.4) feature is enabled in the Nearest Bridge (8.6.3) to each Talker and Listener. Therefore, when a Talker or Listener uses an enhanced feature, the success or failure of the Stream reservation depends on the externalControl (12.32.4.1) parameter on the Port connected to the Talker/Listener, as follows:

a) externalControl TRUE

SRP messages are exchanged with the CNC, and the CNC uses those SRP messages to learn the requirements for each Stream. The CNC uses remote management protocols (e.g., SNMP, NETCONF) in order to learn the capabilities of the Bridges between each Talker and its Listeners. The CNC is not required to support all Bridge features, but for the Bridge features that it supports, it compares the Bridge's capabilities to the configuration needed in order to meet each Stream's requirements. If the CNC successfully configures the Bridges for the Stream, the CNC shall use MRP External Control to declare a Talker Advertise attribute to each Listener and a Listener Ready attribute to the Talker. If the CNC fails to configure the Bridges for the Stream, the CNC shall use MRP External Control to declare a Talker Failed attribute to each Listener and a Listener Ready Failed or Listener Asking Failed attribute to the Talker.

b) externalControl FALSE

When MRP External Control is not used, SRP messages propagate through Bridges, and the Bridges configure themselves for the Stream reservation. Some enhanced features can be supported with this model, and other enhanced features cannot be supported. In the specifications of this subclause, the phrase "When the externalControl attribute is FALSE" is used to specify failure conditions when MRP External Control is not used for the Talker/Listener. If this phrase is not used, the feature is fully supported in the absence of MRP External Control (i.e., CNC).

35.2.2.10.1 Structure definition

The FirstValue of each attribute shall consist of a list of one or more TLVs. Each TLV shall contain a single octet TLV type, followed by a single octet TLV length, followed by multiple octets for the TLV value.

The TLV type shall use a value specified in Table 35-7.

Table 35-7—TLV types

TLV	TLV type	TLV length
Talker	1	variable
StreamID	2	8
StreamRank	3	1
EndStationInterfaces	4	variable
InterfaceID	5	variable
DataFrameSpecification	6	18
IEEE802-MacAddresses	7	12
IEEE802-VlanTag	8	2
IPv4-tuple	9	15
IPv6-tuple	10	39
TrafficSpecification	11	9
TSpecTimeAware	12	12
UserToNetworkRequirements	13	5
InterfaceCapabilities	14	variable
Listener	15	variable
Status	16	variable
StatusInfo	17	3
AccumulatedLatency	18	4
InterfaceConfiguration	19	variable
TimeAwareOffset	20	4
FailedInterfaces	21	variable

The TLV length shall contain the number of octets in the TLV value that follows. The TLV value is specified in subsequent subclauses for each TLV.

The following Backus-Naur Form (BNF) production gives the formal description of the MSRPDU FirstValue structure for the Talker Enhanced attribute:

TalkerEnhanced_FirstValue ::= Talker, Status
Talker ::= Type, Length,
StreamID,
StreamRank,
[EndStationInterfaces,]
[DataFrameSpecification,]
TrafficSpecification,
[TSpecTimeAware,]
[UserToNetworkRequirements,]
[InterfaceCapabilities,]
Status ::= Type, Length,
StatusInfo,
AccumulatedLatency
[InterfaceConfiguration]
[FailedInterfaces]
StreamID ::= Type, Length, *value specified in 35.2.2.10.2*
StreamRank ::= Type, Length, *value specified in 35.2.2.10.3*
EndStationInterfaces ::= Type, Length, *value specified in 35.2.2.10.4*, *35.2.2.10.4*
DataFrameSpecification ::= Type, Length, *value specified in 35.2.2.10.5*, *35.2.2.10.5*
TrafficSpecification ::= Type, Length, *value specified in 35.2.2.10.6*
TSpecTimeAware ::= Type, Length, *value specified in 35.2.2.10.6*
UserToNetworkRequirements ::= Type, Length, *value specified in 35.2.2.10.7*
InterfaceCapabilities ::= Type, Length, *value specified in 35.2.2.10.8*, *35.2.2.10.8*
StatusInfo ::= Type, Length, *value specified in 35.2.2.10.9*
AccumulatedLatency ::= Type, Length, *value specified in 35.2.2.10.10*
InterfaceConfiguration ::= Type, Length, *value specified in 35.2.2.10.11*
FailedInterfaces ::= Type, Length, *value specified in 35.2.2.10.12*
Type BYTE ::= *corresponding TLV Type from Table 35-7*
Length BYTE ::= *corresponding TLV Length (number of octets in TLV Value)*

The following Backus-Naur Form (BNF) production gives the formal description of the MSRPDU FirstValue structure for the Listener Enhanced attribute:

ListenerEnhanced_FirstValue ::= Listener, Status
Listener ::= Type, Length,
StreamID,
[EndStationInterfaces,]
[UserToNetworkRequirements,]
[InterfaceCapabilities]
StatusGroup ::= Type, Length,
StatusInfo,
[InterfaceConfiguration]
[FailedInterfaces]
StreamID ::= Type, Length, *value specified in 35.2.2.10.2*
EndStationInterfaces ::= Type, Length, *value specified in 35.2.2.10.4, 35.2.2.10.4*
UserToNetworkRequirements ::= Type, Length, *value specified in 35.2.2.10.7*
InterfaceCapabilities ::= Type, Length, *value specified in 35.2.2.10.8, 35.2.2.10.8*
StatusInfo ::= Type, Length, *value specified in 35.2.2.10.9*
InterfaceConfiguration ::= Type, Length, *value specified in 35.2.2.10.11*
FailedInterfaces ::= Type, Length, *value specified in 35.2.2.10.12*
Type BYTE ::= *corresponding TLV Type from Table 35-7*
Length BYTE ::= *corresponding TLV Length (number of octets in TLV value)*

35.2.2.10.2 StreamID

The StreamID group is specified in 46.2.3.1.

Figure 35-4 specifies the encoding of the value for the StreamID TLV.

	Octet	Length
MacAddress	1	6
UniqueID	7	2

Figure 35-4—Value of StreamID TLV

The MacAddress is encoded in a manner consistent with the MAC address of a frame header.

The semantics of the MacAddress and UniqueID elements of the enhanced StreamID TLV are the same as the semantics of the Mac Address and Unique ID of the original StreamID structure (35.2.2.8.2).

Requirements for incrementing UniqueID are specified in 35.2.2.10.

35.2.2.10.3 StreamRank

The StreamRank group is specified in 46.2.3.2.

Figure 35-5 specifies the encoding of the value for the StreamRank TLV.

	Octet	Length
reserved	1	7 bits
Rank	1	1 bit

Figure 35-5—Value of StreamRank TLV

The semantics of the Rank element of the enhanced StreamRank TLV are the same as the semantics of the Rank of the original PriorityAndRank structure (35.2.2.8.5).

35.2.2.10.4 EndStationInterfaces

The EndStationInterfaces group is specified in 46.2.3.3.

The Value of the EndStationInterfaces TLV shall consist of one or more InterfaceID TLVs. An InterfaceID TLV is provided for each interface used by the Stream’s Talker/Listener.

Figure 35-6 specifies the encoding of the value for the InterfaceID TLV.

Group length: 6 + NameLength	Octet	Length
MacAddress	1	6
InterfaceName	7	NameLength

Figure 35-6—Value of InterfaceID TLV

The MacAddress is encoded in a manner consistent with the MAC address of a frame header.

If the InterfaceName element is not used, its NameLength is zero, and InterfaceName does not exist in the InterfaceID’s Value.

EndStationInterfaces does not exist in the original Attribute Types (MSRPv0). EndStationInterfaces enhances MSRP for optional support of CNC.

EndStationInterfaces specifies the identification of physical interfaces (distinct points of attachment) in the end station acting as a Talker/Listener. EndStationInterfaces is used by the CNC to locate the Talker/Listener in the topology. EndStationInterfaces can also be used by end stations with two or more interfaces.

When the externalControl attribute is TRUE (12.32.4.1), EndStationInterfaces should be included in the attribute declared by the Talker or Listener. If the CNC does not have the information needed to identify the Talker/Listener Ports in the topology, the CNC is likely to fail the Stream reservation (35.2.2.10).

When the externalControl attribute is FALSE (12.32.4.1), if EndStationInterfaces contains more than one interface, the Nearest Bridge shall fail the Stream reservation. The fully distributed model does not specify support for multiple interfaces. To fail the Stream reservation, the Nearest Bridge shall change Talker Advertise to Talker Failed and report Failure Code=25 (Table 46-15) and also change Listener Ready or Listener Ready Failed to Listener Asking Failed and report Failure Code=25.

Since the EndStationInterfaces is only used by MRP External Control (12.32.4) for communication with a CNC, the EndStationInterfaces TLV shall be removed from the MSRP FirstValue prior to propagation with MAP (35.2.4).

35.2.2.10.5 DataFrameSpecification

The DataFrameSpecification group is specified in 46.2.3.4.

The TLV for DataFrameSpecification shall consist of Type and Length, followed by a Value that consists of a list of one or more TLVs for each field in the user's frame. The list of TLVs within the DataFrameSpecification value shall be ordered from start of frame to end of header.

Figure 35-7 specifies the encoding of the value for the IEEE802-MacAddresses TLV. The MAC addresses are encoded in a manner consistent with the MAC address of a frame header.

	Octet	Length
DestinationMacAddress	1	6
SourceMacAddress	7	6

Figure 35-7—Value of IEEE802-MacAddresses TLV

Figure 35-8 specifies the encoding of the value for the IEEE802-VlanTag TLV.

	Octet	Length
Priority Code Point	1	3 bits
Reserved	1	1 bit
VLAN ID	1	12 bits

Figure 35-8—Value of IEEE802-VlanTag TLV

Figure 35-9 specifies the encoding of the value for the IPv4-tuple TLV. The IP addresses are encoded in a manner consistent with the IP address of a packet header.

	Octet	Length
SourceIpAddress	1	4
DestinationIpAddress	5	4
Dscp	9	1
Protocol	10	2
SourcePort	12	2
DestinationPort	14	2

Figure 35-9—Value of IPv4-tuple TLV

Figure 35-10 specifies the encoding of the value for the IPv6-tuple TLV. The IP addresses are encoded in a manner consistent with the IP address of a packet header.

	Octet	Length
SourceIpAddress	1	16
DestinationIpAddress	17	16
Dscp	33	1
Protocol	34	2
SourcePort	36	2
DestinationPort	38	2

Figure 35-10—Value of IPv6-tuple TLV

The semantics of the DestinationMacAddress of the enhanced DataFrameSpecification TLV (IEEE802-MacAddresses sub-TLV) are the same as the semantics of the destination_address of the original DataFrameParameters structure (35.2.2.8.3). The semantics of the VlanId of the enhanced DataFrameSpecification TLV (IEEE802-VlanTag sub-TLV) are the same as the semantics of the vlan_identifier of the original DataFrameParameters structure (35.2.2.8.3). The semantics of the PriorityCodePoint element of the enhanced DataFrameSpecification TLV are the same as the semantics of the Data Frame Priority of the original PriorityAndRank structure (35.2.2.8.5).

Requirements for incrementing destination addresses of DataFrameSpecification are specified in 35.2.2.10.

In order to apply TSN behavior to Streams (e.g., reserved bandwidth guarantees), MSRP must be able to distinguish one Stream from another Stream and to distinguish Streams from non-TSN traffic (e.g., best-effort). This requires unique identification of each Stream within the user (i.e., Talker and Listener) as well as the network (i.e., Bridges).

As compared to the original Attribute Types (MSRPv0), the enhancements of the DataFrameSpecification TLV support Stream transformation (46.1.4).

Stream transformation is an optional feature in MSRP Participants. Since Stream Transformation can be supported in either end station or Bridge, one of the following methodologies may be chosen:

a) No Stream Transformation

When Stream transformation (46.1.4) is not supported, the user's identification of the Stream must be the same as the network's identification (i.e., destination MAC address and VLAN ID). This is the methodology used for MSRPv0. This methodology requires the following in each end station (Talker/Listener):

1) The destination MAC address of the user's data frame shall be either multicast (group) or a locally administered unicast (individual). A multicast MAC address is allocated by the user (e.g., a higher layer protocol like IEEE Std 1722 [B16]). Only one Stream is allowed per destination MAC address. The destination MAC address shall be provided as the DestinationMacAddress element of the IEEE802-MacAddresses sub-TLV of the DataFrameSpecification TLV.

   NOTE—When Stream transformation is not supported, MSRP prohibits a DestinationMacAddress element that is universal unicast (i.e., individual MAC address of the Listener). Since the Listener's universal unicast MAC address is used for non-TSN traffic, it does not uniquely identify the Stream. The VLAN ID alone does not distinguish the Stream's traffic because Bridges can be configured to egress non-TSN traffic using the same VLAN ID that the Stream is using.

2) The Talker uses its individual MAC address as the source MAC address of the data frame. The source MAC address shall be provided as the SourceMacAddress element of the IEEE802-MacAddresses sub-TLV of the DataFrameSpecification TLV.
3) The data frame shall use a VLAN tag containing a Priority Code Point (PCP) and a VLAN ID, both provided in the IEEE802-VlanTag sub-TLV of the DataFrameSpecification TLV. The Talker uses the value SRclassPriority of the Domain attribute (35.2.2.9.3) for the PriorityCodePoint. If the Talker has knowledge of a specific VLAN ID to use, any valid VlanId can be specified (1 to 4094). If the Talker does not have knowledge of a specific VLAN ID to use, the VlanId uses the value from the SRclassVID of the Domain attribute (35.2.2.9.4).

b) Stream Transformation in end station

When Stream transformation (46.1.4) is performed in the end station (Talker/Listener), the end station relies on the network to provide the network's identification of the Stream (i.e., destination MAC address and VLAN ID). The network identification is provided by the CNC through the use of MRP External Control (12.32.4) in the Nearest Bridge (8.6.3). This methodology requires the following in each end station (Talker/Listener):

1) The Talker's DataFrameSpecification TLV shall not be included in the Talker attribute. This indicates to the CNC that Stream transformation is performed in the end station. Since the user's data frame identification is not used in the network, the DataFrameSpecification is not relevant to Bridges.
2) The end station's InterfaceCapabilities TLV (46.2.3.7) shall set VlanTagCapable=true and CB-StreamIdenTypeList containing the Active Destination MAC and VLAN Stream identification type (46.2.3). If the user's data frame uses either IPv4-tuple or IPv6-tuple, the CB-StreamIdenTypeList shall contain the IP Stream identification type. These InterfaceCapabilities specify that the end station supports the IEEE 802.1CB stream identification functions that transform between the user's identification and the corresponding network identification.
3) When the externalControl attribute is FALSE (12.32.4.1), if the Talker's DataFrameSpecification TLV is missing from Talker Advertise, the Nearest Bridge shall fail the Stream reservation. The fully distributed model does not specify support for stream transformation in end station. To fail the Stream reservation, the Nearest Bridge shall change Talker Advertise to Talker Failed and report Failure Code=22 (Table 46-15).
4) The CNC shall allocate a multicast MAC address for the network identification and use MRP External Control to declare an MSRP attribute containing a InterfaceConfiguration sub-TLV (35.2.2.10.11) with configuration values for IEEE802-MacAddresses and IEEE802-VlanTag.

These configuration values provide the network identification for the end station's transformation. For an end station acting as Talker, the Nearest Bridge includes InterfaceConfiguration in the declared Listener Ready or Listener Ready Failed. For an end station acting as Listener, the Nearest Bridge includes InterfaceConfiguration in the declared Talker Advertise.

5) When the Stream is withdrawn (i.e., MRP Leave of Talker Advertise), the CNC can free the multicast MAC address for use by subsequent Streams.

c) Stream Transformation in Bridge

When Stream transformation (46.1.4) is performed in the Bridge, the end station relies on the CNC to configure the Bridge to perform all transformation. The user identification (i.e., DataFrameSpecification) is provided to the CNC through the use of MRP External Control (12.32.4) in the Nearest Bridge (8.6.3). The CNC uses management to configure IEEE 802.1CB features in the Nearest Bridge to transform the Stream between user and network identification. This methodology requires the following:

1) The Talker's DataFrameSpecification TLV provides unique user identification of the Stream, but that user identification does not meet the requirements for no stream transformation [item a) in 35.2.2.10.5]. If the destination address alone does not distinguish the Stream from other Streams and non-TSN traffic, other elements of the DataFrameSpecification shall be unique. For example, if the data frame is untagged with unicast DestinationMacAddress and unicast DestinationIpAddress, a unique DestinationPort can distinguish the Stream.
2) When the externalControl attribute is FALSE (12.32.4.1), since the Talker's DataFrameSpecification TLV does not meet the requirements for no stream transformation [item a) in 35.2.2.10.5], the Nearest Bridge shall fail the Stream reservation. The fully distributed model does not specify support for stream transformation in Bridge. To fail the Stream reservation, the Nearest Bridge shall change Talker Advertise to Talker Failed and report Failure Code=22 (Table 46-15).
3) If the CNC determines that the Nearest Bridge does not support IEEE Std 802.1CB, it shall use MRP External Control to declare an MSRP attribute containing a StatusInfo sub-TLV (35.2.2.10.9) with Failure Code=23 (Table 46-15). For an end station acting as Talker, the Nearest Bridge declares Listener Asking Failed. For an end station acting as Listener, the Nearest Bridge declares Talker Failed.
4) If the CNC determines that the Nearest Bridge does not support the IEEE 802.1CB stream identification types for the DataFrameSpecification, it shall use MRP External Control to declare an MSRP attribute containing a StatusInfo sub-TLV (35.2.2.10.9) with Failure Code=24 (Table 46-15). For an end station acting as Talker, the Nearest Bridge declares Listener Asking Failed. For an end station acting as Listener, the Nearest Bridge declares Talker Failed.
5) If the CNC successfully configures the IEEE 802.1CB stream identification types for the DataFrameSpecification, it shall use MRP External Control to declare a successful MSRP attribute (assuming no other failures). For an end station acting as Talker, the Nearest Bridge declares Listener Ready or Listener Ready Failed. For an end station acting as Listener, the Nearest Bridge declares Talker Advertise.
6) When the Stream is withdrawn (i.e., MRP Leave of Talker Advertise), the CNC can free the multicast MAC address for use by subsequent Streams. The CNC can also remove IEEE 802.1CB configurations for the withdrawn Stream.

35.2.2.10.6 TrafficSpecification and TSpecTimeAware

The TrafficSpecification group and optional TSpecTimeAware group are specified in 46.2.3.5.

The TrafficSpecification shall consist of a required TrafficSpecification TLV, followed by an optional TSpecTimeAware TLV.

Figure 35-11 specifies the encoding of the value for the TrafficSpecification TLV.

	Octet	Length
Interval	1	4
MaxFramesPerInterval	5	2
MaxFrameSize	7	2
TransmissionSelection	9	1

Figure 35-11—Value of TrafficSpecification TLV

Figure 35-12 specifies the encoding of the value for the TSpecTimeAware TLV. The presence of the optional TSpecTimeAware TLV is handled as specified in 46.2.3.5 for the presence of the TSpecTimeAware group.

	Octet	Length
EarliestTransmitOffset	1	4
LatestTransmitOffset	5	4
Jitter	9	4

Figure 35-12—Value of TSpecTimeAware TLV

The semantics of the MaxFramesPerInterval element of the enhanced TrafficSpecification TLV are the same as the semantics of the MaxIntervalFrames of the original TSpec structure (35.2.2.8.4). The semantics of the MaxFrameSize element of the enhanced TrafficSpecification TLV are the same as the semantics of the MaxFrameSize of the original TSpec structure (35.2.2.8.4).

A Talker that assumes usage of the fully distributed model should use TrafficSpecification as follows:

a) Set the Interval element of the TrafficSpecification TLV to the classMeasurementInterval (34.3) of the stream's SR class (35.2.2.9.2).
b) Set the TransmissionSelection element to the value 1 for use of the credit-based shaper (8.6.8.2).
c) Do not use the TSpecTimeAware TLV.

When the externalControl attribute is FALSE (12.32.4.1), if the Talker's TrafficSpecification TLV does not meet the preceding recommendations a) through c), a Bridge may fail the Stream reservation. Bridges using the fully distributed model are not required to support Talker-specific intervals or shaping beyond those of MSRPv0. To fail the Stream reservation, the Bridge shall change Talker Advertise to Talker Failed and report Failure Code=25 (Table 46-15).

NOTE—In IEEE Std 802.1BA [B9], the AccumulatedLatency computation assumes consistent use of the credit-based shaper at the classMeasurementInterval for the Talker and all Bridges using the SR class. This assumption aligns with the preceding recommendations. The Talker's TrafficSpecification specifies the interval, shaping, and/or scheduling of the Talker only, and TrafficSpecification does not change as it propagates through Bridges. Therefore, when MRP External Control is not in use, in order to support TrafficSpecifications beyond those of IEEE Std 802.1BA, each Bridge must be able to 1) distinguish whether the Port registering Talker Advertise is connected directly to the Talker (i.e., end station) or another Bridge, to determine where TrafficSpecification impacts the AccumulatedLatency, and 2) understand the shaping and scheduling used in each Bridge in the path from Talker to the current Bridge since that also impacts AccumulatedLatency. Specifications for these tasks are not provided in this standard.

35.2.2.10.7 UserToNetworkRequirements

The UserToNetworkRequirements group is specified in 46.2.3.6.

Figure 35-13 specifies the encoding of the value for the UserToNetworkRequirements TLV.

	Octet	Length
NumSeamlessTrees	1	1
MaxLatency	2	4

Figure 35-13—Value of UserToNetworkRequirements TLV

UserToNetworkRequirements does not exist in the original Attribute Types (MSRPv0). UserToNetworkRequirements provides an optional mechanism for the Stream's Talker and/or Listeners to specify requirements to the network.

As specified in the MSRP structure definition (35.2.2.10.1), the UserToNetworkRequirements TLV may be used for either Talker or Listener attributes.

If UserToNetworkRequirements.MaxLatency is greater than zero, when an MSRP Participant detects that the AccumulatedLatency (35.2.2.10.10) of the Stream is greater than UserToNetworkRequirements.MaxLatency, the Stream's status is reported as failed (35.2.4.6).

If UserToNetworkRequirements.MaxLatency is zero (or UserToNetworkRequirements is not provided), when an MSRP Participant detects that the AccumulatedLatency of the Stream is greater than the initial AccumulatedLatency when the Stream was successfully configured, the Stream's status is reported as failed. This technique is compatible with MSRPv0 (35.2.2.8.6).

As specified in 46.2.3.6 and 35.2.4.6, UserToNetworkRequirements.MaxLatency specified by a Talker applies to all Listeners of the stream. UserToNetworkRequirements.MaxLatency specified by a Listener applies to that Listener alone.

Additional specifications for UserToNetworkRequirements.MaxLatency are provided in 35.2.6.

A Talker that assumes usage of the fully distributed model should use UserToNetworkRequirements as follows:

a) Set the NumSeamlessTrees element to one.

When the externalControl attribute is FALSE (12.32.4.1), if the Talker's UserToNetworkRequirements TLV does not meet the preceding recommendation a), a Bridge may fail the Stream reservation. Bridges using the fully distributed model are not required to support configuration of seamless redundancy. To fail the Stream reservation, the Bridge shall change Talker Advertise to Talker Failed and report Failure Code=25 (Table 46-15).

NOTE—NumSeamlessTrees greater than one is intended for use with MRP External Control (i.e., externalControl TRUE), which passes SRP attributes to a CNC, and the CNC configures Bridges for seamless redundancy (e.g., IEEE Std 802.1CB or IEC 62439-3:2016 [B4]). When MRP External Control is not in use, in order to support NumSeamlessTrees greater than one, each Bridge must be able to either 1) determine that seamless redundancy has already been configured for all Bridges between the Talker and its Listeners or 2) solicit such configuration from an external entity. Specifications for these tasks are not provided in this standard.

35.2.2.10.8 InterfaceCapabilities

The InterfaceCapabilities group is specified in 46.2.3.7.

Figure 35-14 specifies the encoding of the value for the InterfaceCapabilities TLV. NumITL represents the number of elements in the CB-StreamIdenTypeList. NumSTL represents the number of elements in the CB-SequenceTypeList.

TLV Length: 3 + (4 × NumITL) + (4 × NumSTL)	Octet	Length
reserved	1	7 bits
VlanTagCapable	1	1 bit
NumITL	2	1
NumSTL	3	1
CB-StreamIdenTypeList	4	4 × NumITL
CB-SequenceTypeList	4	4 × NumITL

Figure 35-14—Value of InterfaceCapabilities TLV

InterfaceCapabilities does not exist in the original Attribute Types (MSRPv0). InterfaceCapabilities provides an optional mechanism for stream transformation as specified in 35.2.2.10.5.

The InterfaceCapabilities TLV is used only for negotiation between an end station and the neighboring MRP Participant on the link. The InterfaceCapabilities TLV shall be removed from the MSRP FirstValue prior to propagation with MAP (35.2.4).

35.2.2.10.9 StatusInfo

The StatusInfo group is specified in 46.2.5.1.

Figure 35-15 specifies the encoding of the value for the StatusInfo TLV.

	Octet	Length
TalkerStatus	1	1
ListenerStatus	2	1
FailureCode	3	1

Figure 35-15—Value of StatusInfo TLV

The semantics of the FailureCode element of the enhanced StatusInfo TLV are the same as the semantics of the Failure Code of the original FailureInformation structure (35.2.2.8.7), and both use the same Table 46-15 for values.

The original Attribute Types (MSRPv0) did not provide a FailureCode from a Listener. The enhanced StatusInfo provides a mechanism for a Listener to provide a FailureCode as status to the Talker.

The StatusInfo in the Talker attribute is used to communicate status information to Listeners. The StatusInfo in the Listener attribute is used to communicate status information to the Talker. In SRP, status flows in one direction. Unless stated otherwise in these specifications, elements of StatusInfo are not copied from a Talker attribute to a Listener attribute, or vice versa.

A StatusInfo TLV for Declaration Type (35.2.1.3) of Talker Advertise shall use a TalkerStatus of Ready.

A StatusInfo TLV for Declaration Type of Talker Failed shall use a TalkerStatus of Failed.

A StatusInfo TLV for Declaration Type of Listener Asking Failed shall use a ListenerStatus of Failed.

A StatusInfo TLV for Declaration Type of Listener Ready shall use a ListenerStatus of Ready.

A StatusInfo TLV for Declaration Type of Listener Ready Failed shall use a ListenerStatus of PartialFailed.

For Talker and Listener attributes, the value for the FailureCode element is specified in Table 46-15.

Refer to 35.2.4.4.6 for information on merging nonzero FailureCode values from multiple Listeners.

NOTE—MSRPv1 adds new values for FailureCode (Table 46-15) that did not exist in MSRPv0 (i.e., 20 and higher). MSRPv0 participants that register Talker Failed with these values are expected to handle the failure without complete understanding of the cause.

35.2.2.10.10 AccumulatedLatency

The AccumulatedLatency group is specified in 46.2.5.2.

Figure 35-16 specifies the encoding of the value for the AccumulatedLatency TLV.

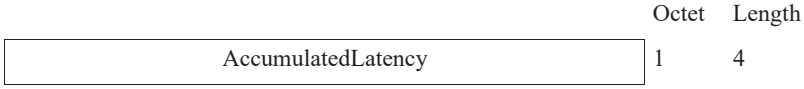

Figure 35-16—Value of AccumulatedLatency TLV

The semantics of the enhanced AccumulatedLatency TLV are the same as the semantics of the original Accumulated Latency structure (35.2.2.8.6).

The original Attribute Types (MSRPv0) failed the Stream when Accumulated Latency increased beyond its initial value. In addition to supporting that mechanism by default, the enhanced AccumulatedLatency (MSRPv1) provides an optional mechanism to fail the Stream when AccumulatedLatency exceeds specified UserToNetworkRequirements for MaxLatency (35.2.2.10.7).

35.2.2.10.11 InterfaceConfiguration

The InterfaceConfiguration group is specified in 46.2.5.3.

The encoding of the value for the InterfaceConfiguration TLV consists of one or more interface configurations. Each interface configuration consists of a single InterfaceID TLV (35.2.2.10.4), followed by a list of configuration values for that interface.

The values in each InterfaceID shall match one of the InterfaceID entries in the Talker/Listener EndStationInterfaces group.

The list of configuration values uses zero or more of the following TLVs:

— IEEE802-MacAddresses TLV (35.2.2.10.5)
— IEEE802-VlanTag TLV (35.2.2.10.5)
— IPv4-tuple TLV (35.2.2.10.5)
— IPv6-tuple TLV (35.2.2.10.5)
— TimeAwareOffset TLV with a value as specified in Figure 35-17

Group length: 4	Octet	Length
TimeAwareOffset	1	4

Figure 35-17—Value of TimeAwareOffset TLV

InterfaceConfiguration does not exist in the original Attribute Types (MSRPv0). InterfaceConfiguration provides an optional mechanism for stream transformation as specified in 35.2.2.10.5.

The InterfaceConfiguration TLV is used only for negotiation between an end station and the neighboring MRP Participant on the link. The InterfaceConfiguration TLV shall be removed from the MSRP FirstValue prior to propagation with MAP (35.2.4).

35.2.2.10.12 FailedInterfaces

The FailedInterfaces group is specified in 46.2.5.4.

The FailedInterfaces TLV may be contained within the Talker or Listener attribute. When a failure occurs in network configuration (i.e., nonzero FailureCode in StatusInfo TLV), FailedInterfaces provides a list of one or more physical interfaces (distinct points of attachment) in the failed Bridge or end station. Each entry in the list is sufficient to locate the interface in the physical topology.

The Value of the FailedInterfaces TLV consists of a sequence of zero or more TLV entries, and each TLV entry uses the InterfaceID TLV specified in 35.2.2.10.4.

The semantics of the enhanced FailedInterfaces TLV is similar to the system identifier of the original FailureInformation structure (35.2.2.8.7), but with enhanced ability to identify more than one failed interface.

The FailedInterfaces TLV is associated with the single FailureCode in the StatusInfo TLV, and it is not used to communicate multiple failures.

Elements of FailedInterfaces are not copied from a Talker attribute to a Listener attribute, or vice versa.

35.2.3 Provision and support of Stream registration service

35.2.3.1 Initiating MSRP registration and deregistration

MSRP utilizes the following five declaration types (35.2.1.3) to communicate: Talker Advertise, Talker Failed, Listener Ready, Listener Ready Failed, and Listener Asking Failed.

When a Port's *neighborProtocolVersion* is 0x00, declarations shall use only the original Attribute Types (35.2.2.8). When a Port's *neighborProtocolVersion* is 0x01 or higher, declarations shall use either the original Attributes Types or the enhanced Attributes Types (35.2.2.10).

An end station behaving as a Talker will send a Talker Advertise declaration to inform the network about the characteristics of the Stream it can provide. Bridges register this declaration, update some of the information contained within the Talker declaration, and forward it out the nonblocked (35.1.3.1) Ports on the Bridge. If *talkerPruning* is enabled and the Bridge has the Stream's destination_address registered on one or more Ports (e.g., using MMRP) it shall only forward the declarations out those Ports. Eventually the Talker declaration will be registered by other end stations.

If *talkerPruning* is enabled and the Stream's destination_address is not registered on any Ports the Talker declaration shall not be forwarded (35.2.4.3.2). When the *talkerPruning* parameter is disabled (false) for the Bridge, each Port provides a *talkerPruningPerPort* parameter to control MAC address pruning for that Port (35.2.4.3.3).

If *talkerVlanPruning* is enabled (35.2.4.3.4), the Bridge will limit the Talker declarations to Ports that have the Stream's VLAN identifier [item b) in 35.2.2.8.3] registered as a member in the VLAN Registration Entries (8.8).

An end station behaving as a Listener will receive the Talker Advertise declaration and register it. If the Listener is interested in receiving that Stream it will send a Listener Ready declaration back toward the Talker. The Bridge's MSRP MAP function will use the StreamID (35.2.2.8.2, 35.2.2.10.2) to associate the Listener Ready with the Talker Advertise and forward the Listener Ready declaration only on the Port that registered the Talker Advertise. This is referred to as Listener Pruning since the declarations are not forwarded out any other Ports. The Bridge will also reserve the required bandwidth and configure its queues and the FDB.

If any Bridge along the path from Talker to Listener does not have sufficient bandwidth or resources available its MSRP MAP function will change the Talker Advertise declaration to a Talker Failed declaration before forwarding it. Similarly a Listener Ready declaration will be changed to a Listener Asking Failed declaration if there is not sufficient bandwidth or resources available. This way both the Talker and Listener will know whether the reservation was successful.

In the case where there is a Talker attribute and Listener attribute(s) registered within a Bridge for a StreamID and a MAD_Leave.request is received for the Talker attribute, the Bridge shall act as a proxy for the Listener(s) and automatically generate a MAD_Leave.request back toward the Talker for those Listener attributes. This is a special case of the behavior described in 35.2.4.4.1.

Finally, there is the Listener Ready Failed declaration. This is used when there are two or more Listeners for a Stream. To simplify the explanation assume there are only two Listeners and one has sufficient bandwidth back to the Talker (signified by a Listener Ready), and the other does not (signified by a Listener Asking Failed). At some point in the network topology there will be a single Bridge that will receive the Listener Ready on one port from the first Listener and the Listener Asking Failed on another port from the second Listener. That Bridge's MSRP MAP function will merge (35.2.4.4.3) those two declarations into a single Listener Ready Failed declaration that will be forwarded to the Talker. When the Talker receives the Listener Ready Failed it will know there are one or more Listeners that want the Stream and can receive it, and there are one or more Listeners that want the Stream but have insufficient bandwidth or resources somewhere along the path to receive it. The Talker may still send the Stream, but it will realize that not all Listeners are going to receive it.

MSRP provides a set of Service Primitives that control the declarations of the attributes defined previously. The primitives associated with the Talker application entities are summarized in Table 35-8. Listener application entities have a corresponding set of primitives summarized in Table 35-9.

Table 35-8—Summary of Talker primitives

Name	Request	Indication
REGISTER_STREAM	35.2.3.1.1	—
DEREGISTER_STREAM	35.2.3.1.3	—
REGISTER_ATTACH	—	35.2.3.1.6
DEREGISTER_ATTACH	—	35.2.3.1.8

Table 35-9—Summary of Listener primitives

Name	Request	Indication
REGISTER_STREAM	—	35.2.3.1.2
DEREGISTER_STREAM	—	35.2.3.1.4
REGISTER_ATTACH	35.2.3.1.5	—
DEREGISTER_ATTACH	35.2.3.1.7	—

35.2.3.1.1 REGISTER_STREAM.request

A Talker application entity shall issue a REGISTER_STREAM.request to the MSRP Participant to initiate the advertisement of an available Stream.

A Talker may choose to enter a nonzero value in the Accumulated Latency that indicates the amount of latency in nanoseconds that a Stream will encounter before being passed to the MAC Service interface.

On receipt of a REGISTER_STREAM.request the MSRP Participant shall issue a MAD_Join.request service primitive (10.2, 10.3). The attribute_type (10.2) parameter of the request shall carry the appropriate Talker Attribute Type (35.2.2.4), depending on the Declaration Type and *neighborProtocolVersion*. The attribute_value (10.2) parameter shall carry the values from the REGISTER_STREAM.request primitive.

```
REGISTER_STREAM.request (
                         StreamID,
                         Declaration Type,
                         DataFrameParameters,
                         TSpec,
                         Data Frame Priority,
                         Rank,
                         Accumulated Latency,
                         FailureInformation
                         )
```

35.2.3.1.2 REGISTER_STREAM.indication

A REGISTER_STREAM.indication notifies the Listener application entity that the referenced Stream is being advertised by a Talker somewhere on the attached network.

On receipt of a MAD_Join.indication service primitive (10.2, 10.3) with an attribute_type of Talker Advertise, Talker Failed, or Talker Enhanced (35.2.2.4), the MSRP application shall issue a REGISTER_STREAM.indication to the Listener application entity. The REGISTER_STREAM.indication shall carry the values from the attribute_value parameter.

```
REGISTER_STREAM.indication (
                           StreamID,
                           Declaration Type,
                           DataFrameParameters,
                           TSpec,
                           Data Frame Priority,
                           Rank,
                           Accumulated Latency,
                           FailureInformation
                           )
```

35.2.3.1.3 DEREGISTER_STREAM.request

A Talker application entity shall issue a DEREGISTER_STREAM.request to the MSRP Participant to remove the Talker's advertisement declaration, and thus remove the advertisement of a Stream, from the network.

On receipt of a DEREGISTER_STREAM.request the MSRP Participant shall issue a MAD_Leave.request service primitive (10.2, 10.3) with the attribute_type set to the Declaration Type currently associated with the StreamID. The attribute_value parameter shall carry the StreamID and other values that were in the associated REGISTER_STREAM.request primitive.

```
DEREGISTER_STREAM.request (
                          StreamID
                          )
```

35.2.3.1.4 DEREGISTER_STREAM.indication

A DEREGISTER_STREAM.indication notifies the Listener application entity that the referenced Stream is no longer being advertised by a Talker.

On receipt of a MAD_Leave.indication service primitive (10.2, 10.3) with an attribute_type of Talker Advertise, Talker Failed, or Talker Enhanced (35.2.2.4), the MSRP application shall issue a DEREGISTER_STREAM.indication to the Listener application entity.

```
DEREGISTER_STREAM.indication (
                             StreamID
                             )
```

35.2.3.1.5 REGISTER_ATTACH.request

A Listener application entity shall issue a REGISTER_ATTACH.request to the MSRP Participant to request attachment to the referenced Stream.

On receipt of a REGISTER_ATTACH.request the MSRP Participant shall issue a MAD_Join.request service primitive (10.2, 10.3). The attribute_type parameter of the request shall carry the appropriate Listener Attribute Type (35.2.2.4), depending on *neighborProtocolVersion*. The attribute_value shall contain the StreamID and the Declaration Type.

```
REGISTER_ATTACH.request (
                        StreamID,
                        Declaration Type
                        )
```

35.2.3.1.6 REGISTER_ATTACH.indication

A REGISTER_ATTACH.indication notifies the Talker application entity that the referenced Stream is being requested by one or more Listeners.

On receipt of a MAD_Join.indication service primitive (10.2, 10.3) with an attribute_type of Listener (35.2.2.4), the MSRP application shall issue a REGISTER_ATTACH.indication to the Talker application entity. The REGISTER_ATTACH.indication shall carry the values from the attribute_value parameter.

```
REGISTER_ATTACH.indication (
                           StreamID,
                           Declaration Type
                           )
```

35.2.3.1.7 DEREGISTER_ATTACH.request

A Listener application entity shall issue a DEREGISTER_ATTACH.request to the MSRP Participant to remove the request to attach to the referenced Stream.

On receipt of a DEREGISTER_ATTACH.request the MSRP Participant shall issue a MAD_Leave.request service primitive (10.2, 10.3) with the attribute_type set to the appropriate Listener Attribute Type (35.2.2.4). The attribute_value parameter shall carry the StreamID and the Declaration Type currently associated with the StreamID.

```
DEREGISTER_ATTACH.request (
                          StreamID
                          )
```

35.2.3.1.8 DEREGISTER_ATTACH.indication

A DEREGISTER_ATTACH.indication notifies the Talker application entity that the referenced Stream is no longer being requested by any Listeners.

On receipt of a MAD_Leave.indication service primitive (10.2, 10.3) with an attribute_type of Listener (35.2.2.4), the MSRP application shall issue a DEREGISTER_ATTACH.indication to the Talker application entity. The DEREGISTER_ATTACH.indication shall contain the StreamID.

```
DEREGISTER_ATTACH.indication (
                             StreamID
                             )
```

35.2.4 MSRP Attribute Propagation

There is no MSRP MAP function for Domain attributes. MSRP simply declares the characteristics of the SR classes that are supported on the Bridge Port regardless of what has been learned from Domain registrations on other Bridge Ports. Registration of the neighbor's Domain attribute determines the value of the *SRPDomainBoundaryPort* and *neighborProtocolVersion* variables (35.2.1.4).

This clause describes the following:

a) Rules for combining and propagating Listener attributes toward the associated Talker
b) How MSRP adjusts the Talker and Listener attributes before propagating them
c) How MSRP translates Attribute Types when propagating from a ProtocolVersion (35.2.2.1) on a registering Port to a different ProtocolVersion on declaring Ports.

Unless stated otherwise, Talker and Listener attributes are propagated as described in 10.3.

In principle, the MAP performs MSRP Attribute Propagation when any of the following conditions occur:

d) A MAD_Join.indication adds a new attribute to MAD (with the *new* parameter, 10.2, set to TRUE).
e) A MAD_Leave.indication is issued by the MAD.
f) An internal application declaration or withdrawal is made in a station.
g) When the bandwidth of the underlying media changes (see *bandwidthAvailabilityChanged* notification in 34.3.3).
h) A Port becomes an SRP domain core port (3.261).
i) If talkerPruning (35.2.4.3.2) or *talkerPruningPerPort* (35.2.4.3.3) is enabled and there is a change in the MAC Address Registration Entries (8.8.4) of a Port.
j) If *talkerVlanPruning* (35.2.4.3.4) is enabled and there is a change in the VLAN Registration Entries on a Port (8.8).
k) A Port changes its *neighborProtocolVersion* parameter (35.2.1.4(j).

The MSRP MAP function is responsible for adjusting and propagating Talker and Listener attributes throughout the bridged network. It also updates the Dynamic Reservation Entries (8.8.7) to specify which Streams shall be filtered and which shall be forwarded, along with updating the associated *streamAge* [item c) in 35.2.1.4]. The bandwidth associated with those Streams is reported to the queuing algorithms via the *operIdleSlope(N)* parameter [item d) in 34.3] on a per-port per-traffic class basis.

Streams of higher importance are given available bandwidth before streams of lower importance.

If insufficient bandwidth or resources are available the streams destination_address will be filtered and the failure will be noted in the Talker and Listener attributes declared from that Bridge.

A port shall only forward MSRP declarations for SR classes it supports. This will eliminate unnecessary priority remapping for traffic related to unsupported SR classes.

The following subclauses describe what the MSRP MAP function shall accomplish.

35.2.4.1 Stream importance

MSRP utilizes the stream Rank [item b) in 35.2.2.8.5, 35.2.2.10.3] to decide which stream is more important than another.

In the case where two streams have the same Rank, the *streamAge* will be compared. If the Ranks are identical and the *streamAge*s are identical the StreamIDs (35.2.2.8.2, 35.2.2.10.2) will be compared and the numerically lower StreamID is considered to be more important.

35.2.4.2 Stream bandwidth calculations

As referenced in Table 35-5, the bandwidth requirements of a Stream include more than just the amount specified in the REGISTER_STREAM.request (35.2.3.1.1). SRP shall add the *perFrameOverhead* (34.4) associated with the media attached to the port.

If this port is on a Shared Media (35.1.1) the bandwidth requirements may need to be further increased. For example, a Stream transmitted from one station to another may have to be sent across the media twice. One time from the Talker station to the DMN, and a second time from the DMN to the Listener station. In this case the bandwidth requirements would need to be doubled.

The *totalFrameSize* for a stream on an outbound Port is therefore the sum of the following three amounts (doubled if each frame is transmitted on the media twice):

a) MaxFrameSize [item a) in 35.2.2.8.4].
b) *perFrameOverhead* (34.4) associated with the media attached to the port.
c) One (1) additional octet to account for slight differences (up to 200 ppm) in the class measurement interval between neighboring devices.

Multiply *totalFrameSize* by MaxIntervalFrames [item b) in 35.2.2.8.4] to arrive at the associated bandwidth (in bits per second), which is then used to update *operIdleSlope(N)* as shown in Table 35-14.

Streams that are in the Listener Ready or Listener Ready Failed state reduce the amount of bandwidth available to other Streams. Streams that have no Listeners, or the Listeners are in the Asking Failed state, do not reduce available bandwidth for other Streams since the Stream data will not be flowing through this outbound Port. These details are considered when calculating how many Streams can flow through a particular Port. The total amount of bandwidth available to a particular traffic class on a Port is represented by *deltaBandwidth(N)* [item b) in 34.3]. Subclauses 34.3.1 and 34.3.2 describe the relationship of available bandwidth between traffic classes.

35.2.4.3 Talker attribute propagation

Table 35-10 describes the propagation of Talker attributes for a StreamID from one port of a Bridge to another. If no Talker attributes are registered for a StreamID then no Talker attributes for that StreamID will be declared on any other port of the Bridge. If a Talker Failed is registered then it will be propagated as a Talker Failed out all other nonblocked (35.1.3.1) ports on the Bridge.

Table 35-10—Talker attribute propagation per port

		Talker		
		(none)	**Advertise**	**Failed**
Listener	**(none)**	(none)	Talker Advertise or Talker Failed	Talker Failed
	Ready	(none)	Talker Advertise or Talker Failed	Talker Failed
	Ready Failed	(none)	Talker Advertise or Talker Failed	Talker Failed
	Asking Failed	(none)	Talker Advertise or Talker Failed	Talker Failed

Talker Advertise registrations require further processing by the MAP function. MAP will analyze available bandwidth and other factors to determine if the outbound port has enough resources available to support the Stream. MAP will also verify msrpMaxFanInPorts, if nonzero, will not be exceeded. If there are sufficient resources and bandwidth available MAP will declare a Talker Advertise. Otherwise, MAP will declare a Talker Failed on the outbound port and add appropriate FailureInformation.

If the outbound Port is an SRP domain boundary port for a given SR class, then for that SR class, the MAP function shall operate such that any Talker Advertise declaration for that SR class that would otherwise propagate through that Port is converted to a Talker Failed declaration with a failure code of 8 (Table 46-15), meaning "Egress Port is not AVB-capable." The consequence of this behavior is that stream reservations can be established only in circumstances where the Talker and the Listener(s) for the stream are located within the same SRP domain.

35.2.4.3.1 ProtocolVersion Translation

Ports with *neighborProtocolVersion* [item j) in 35.2.1.4] of 0x00 shall use only the original Attribute Types (35.2.2.4) of Talker Advertise and Talker Failed. Ports with *neighborProtocolVersion* of 0x01 or higher shall use either the original Attribute Types or the enhanced Attribute Type of Talker Enhanced.

In order to propagate an enhanced Attribute Type (e.g., registered from a Port with *neighborProtocolVersion* of 0x01) to an original Attribute Type (e.g., declared to a Port with *neighborProtocolVersion* of 0x00), fields of the attribute's FirstValue shall be translated as specified in Table 35-11.

NOTE—Original Attribute Types always propagate without translation, even if *neighborProtocolVersion* is 0x01 or higher.

Table 35-11—Translation of Talker attributes

Enhanced field	Original field	Enhanced to original translation
StreamID, MacAddress	StreamID, MAC Address	No change: Copy the field's contents from enhanced to original without change.
StreamID, UniqueID	StreamID, Unique ID	No change: Copy the field's contents from enhanced to original without change.
StreamRank, Rank	PriorityAndRank, Rank	No change: Copy the field's contents from enhanced to original without change.
EndStationInterfaces	—	Not propagated: This TLV is not propagated through MAP, so translation is not applicable.
DataFrameSpecification, IEEE802-MacAddresses, DestinationMacAddress	DataFrameParameters, destination_address	No change: Copy the field's contents from enhanced to original without change.
DataFrameSpecification, IEEE802-MacAddresses, SourceMacAddress	—	Lost: The declaration type does not change (i.e., fail), because MSRPv0 does not use the source MAC address for Stream identification.
DataFrameSpecification, IEEE802-VlanTag, PriorityCodePoint	PriorityAndRank, Data Frame Priority	No change: Copy the field's contents from enhanced to original without change.
DataFrameSpecification, IEEE802-VlanTag, VlanId	DataFrameParameters, vlan_identifier	No change: Copy the field's contents from enhanced to original without change.

Table 35-11—Translation of Talker attributes *(continued)*

Enhanced field	Original field	Enhanced to original translation
TrafficSpecification, Interval	—	Lost: If this field does not match the default classMeasurementInterval (34.3) of the stream's SR class, a Talker Advertise declaration is converted to a Talker Failed declaration with a failure code of 20.
TrafficSpecification, MaxFramesPerInterval	TSpec, MaxIntervalFrames	No change: Copy the field's contents from enhanced to original without change.
TrafficSpecification, MaxFrameSize	TSpec, MaxFrameSize	No change: Copy the field's contents from enhanced to original without change.
TrafficSpecification, TransmissionSelection	—	Lost: If this field is not one, a Talker Advertise declaration is converted to a Talker Failed declaration with a failure code of 20.
TrafficSpecification, TSpecTimeAware TLV	—	Lost: If this TLV is present, a Talker Advertise declaration is converted to a Talker Failed declaration with a failure code of 20.
UserToNetworkRequirements, NumSeamlessTrees	—	Lost: If this field is not one, a Talker Advertise declaration is converted to a Talker Failed declaration with a failure code of 20.
UserToNetworkRequirements, MaxLatency	—	Lost: If this field is not zero, a Talker Advertise declaration is converted to a Talker Failed declaration with a failure code of 20.
InterfaceCapabilities	—	Not propagated: This TLV is not propagated through MAP, so translation is not applicable.
StatusInfo, TalkerStatus	—	No change: This field determines the original Attribute Type to declare (Talker Advertise or Talker Failed).
StatusInfo, ListenerStatus	—	No change: This field is set according to the ListenerStatus that the Bridge last propagated in the Listener attribute of the Stream. If no Listener attribute has been propagated, this field is set to zero (None).
StatusInfo, FailureCode	FailureInformation, Failure Code	For Talker Failed, this field has no change (i.e., copy from enhanced to original). For Talker Advertise, this field is lost, but the declaration type does not change (i.e., fail).
AccumulatedLatency	AccumulatedLatency, AL	No change: Copy the field's contents from enhanced to original without change.
InterfaceConfiguration	—	Not propagated: This TLV is not propagated through MAP, so translation is not applicable.
FailedInterfaces, MacAddress	FailureInformation, system identifier	No change: This field applies to Talker Failed only. The most significant 16 bits of system identifier are set to zero, and the MacAddress is copied to the least significant 48 bits of system identifier.
FailedInterfaces, InterfaceName	FailureInformation	Lost: This field applies to Talker Failed only.

35.2.4.3.2 Talker Pruning

The *talkerPruning* parameter (35.2.1.4) is disabled by default, and Talker declarations are sent out all nonblocked Ports. If *talkerPruning* is enabled and the destination_address [item a) in 35.2.2.8.3] of the Stream is found in the MAC Address Registration Entries (8.8.4) for the Port, the declaration shall be forwarded. If the destination_address is not found the declaration shall be blocked and no Talker declaration of any type shall be forwarded.

35.2.4.3.3 Talker Pruning Per Port

When the *talkerPruning* parameter is disabled (false) for the Bridge, each Port may provide a *talkerPruningPerPort* parameter (35.2.1.4) to control MAC address pruning for that Port.

When the *talkerPruningPerPort* feature is provided, all *talkerPruningPerPort* parameters are disabled by default.

When *talkerPruning* is enabled (true), the *talkerPruningPerPort* parameters are ignored.

Each *talkerPruningPerPort* parameter controls MAC address pruning for that Port when *talkerPruning* is disabled (false). If *talkerPruningPerPort* is disabled for the Port, Talker declarations are forwarded on that Port regardless of the destination_address [item a) in 35.2.2.8.3] of the Stream. If *talkerPruningPerPort* is enabled for the Port and the destination_address of the Stream is found in the MAC Address Registration Entries (8.8.4) for the Port, the declaration shall be forwarded. If *talkerPruningPerPort* is enabled for the Port and the destination_address of the Stream is not found in the MAC Address Registration Entries for the Port, the declaration shall be blocked, and no Talker declaration of any type shall be forwarded.

35.2.4.3.4 Talker VLAN Pruning

The *talkerVlanPruning* parameter (35.2.1.4) may be provided on the Bridge in order to limit the Talker declarations to Ports that have the Stream's vlan_identifier [item b) in 35.2.2.8.3] registered as a member in the VLAN Registration Entries (8.8).

When the *talkerVlanPruning* feature is provided, it is disabled (false) by default.

When *talkerVlanPruning* is disabled (false), the MAP context for MSRP propagates Talker declarations according to the VLAN spanning tree (35.1.3.1), regardless of the registration of the Stream's vlan_identifier in the Filtering Database (8.8.10). This allows potential Listeners to receive Talker declarations prior to registering the VLAN with MVRP.

When *talkerVlanPruning* is enabled (true), in addition to propagating along the VLAN spanning tree, the MAP context for MSRP filters propagation according to the registration of the Stream's vlan_identifier in the Filtering Database (8.8.10). If *talkerVlanPruning* is enabled and registration of the Stream's vlan_identifier on a Port is not member (Registration Forbidden, Not Registered, or No Dynamic Registration Entry Present), MSRP shall not propagate the declaration on that Port. This propagation is effectively the same as propagation for the Stream's data frames. Potential Listeners can join the VLAN dynamically with MVRP in order to receive Talker declarations for that vlan_identifier (35.1.2.1).

The *talkerVlanPruning* parameter filters by VLAN, and it operates independently from the parameters that filter by MAC address (*talkerPruning* and *talkerPruningPerPort*).

35.2.4.4 Listener attribute propagation

Listener Attributes, unlike Talker Attributes, can be merged (35.2.4.4.3) from several Listeners on different ports into a single Listener declaration. There are two steps involved:

a) Processing of incoming Listener attribute registration on a port based upon the status of the associated Talker attribute registration,
b) Merging all the individual ports Listener attributes gathered in step 1, above, into a single Listener attribute to be declared on the nonblocked (35.1.3.1) outbound port which has the associated Talker registration. If no Talker attribute is registered within the Bridge for the StreamID associated with the Listener, the Listener attribute will not be propagated.

35.2.4.4.1 Incoming Listener attribute processing

Table 35-12 describes how Listener attributes are propagated from the incoming ports.

Table 35-12—Incoming Listener attribute propagation per port

		Talker		
		(none)	**Advertise**	**Failed**
Listener	**(none)**	(none)	(none)	(none)
	Ready	(none)	Listener Ready	Listener Asking Failed
	Ready Failed	(none)	Listener Ready Failed	Listener Asking Failed
	Asking Failed	(none)	Listener Asking Failed	Listener Asking Failed

If no Listener attributes are registered on a particular port then no Listener attribute will be propagated to the Listener attribute merging (35.2.4.4.3) from that port.

If a Listener Asking Failed is registered on a port then it will be propagated as a Listener Asking Failed and merged with other Listener Attributes from other ports.

If no Talker attributes are associated with the Listener attribute, the Listener attribute will not be propagated.

If a Talker Failed is registered on another port for the associated Listener Ready or Listener Ready Failed then a Listener Asking Failed will be propagated and merged with other Listener attributes from other ports.

If a Talker Advertise is registered on another port for the StreamID associated with a Listener Ready or Listener Ready Failed then that Listener attribute will be forwarded as-is and merged with Listener Attributes from other ports.

35.2.4.4.2 Updating Queuing and Forwarding information

When Incoming Listener attribute processing (35.2.4.4.1) has been completed for a port the Dynamic Reservation Entries (8.8.7) shall be updated as shown in Table 35-13.

The *operIdleSlope(N)* [item d) in 34.3] shall be updated as shown in Table 35-14, dependent on the change to the Dynamic Reservation Entries. MSRP MAP processing can occur at any time (35.2.4), resulting in a change to which Streams are filtered and to which streams are forwarded. These changes in bandwidth requirements shall be reflected in the *operIdleSlope(N)* variable. Streams that have had their bandwidth removed shall decrease *operIdleSlope(N)*. Streams that have just been allocated bandwidth shall increase *operIdleSlope(N)*.

NOTE—The order of operations is important when updating the Dynamic Reservation Entries and the *operIdleSlope(N)* in order not to allow any associated streaming frames to be dropped. If the bandwidth utilization of a port is going to be increased (i.e., a Stream is going to be forwarded) the *operIdleSlope(N)* is updated before the Dynamic Reservation Entries. If the bandwidth utilization of a port is going to be decreased (i.e., a Stream is going to be filtered) the Dynamic Reservation Entries are updated before the *operIdleSlope(N)*.

Table 35-13—Updating Dynamic Reservation Entries

		Talker		
		(none)	**Advertise**	**Failed**
Listener	**(none)**	(no entry)	Filtering	Filtering
	Ready	Filtering	Forwarding	Filtering
	Ready Failed	Filtering	Forwarding	Filtering
	Asking Failed	Filtering	Filtering	Filtering

Table 35-14—Updating *operIdleSlope(N)*

		Dynamic Reservation Entries prior to MSRP MAP running		
		(none)	**Filtering**	**Forwarding**
Dynamic Reservation Entries after MSRP MAP running	**(none)**	(no change)	(no change)	Decrease *operIdleSlope(N)*
	Filtering	(no change)	(no change)	Decrease *operIdleSlope(N)*
	Forwarding	Increase *operIdleSlope(N)*	Increase *operIdleSlope(N)*	(no change)

35.2.4.4.3 Merge Listener Declarations

Listener Registrations with the same StreamID shall be merged into a single Listener Declaration that will be declared on the port with the associated Talker registration. If no such Talker registration exists the Listener attribute is not declared. When this Declaration is sent,

a) The Direction (35.2.1.2) is Listener.
b) The Declaration Type (35.2.1.3) is determined according to Table 35-15.
c) The StreamID (35.2.2.8.2) is that of the Listener Registrations.

Table 35-15—Listener Declaration Type Summation

First Declaration Type	Second Declaration Type	Resultant Declaration Type
Ready	none or Ready	Ready
	Ready Failed or Asking Failed	Ready Failed
Ready Failed	any	Ready Failed
Asking Failed	Ready or Ready Failed	Ready Failed
	none or Asking Failed	Asking Failed

35.2.4.4.4 ProtocolVersion Translation

Ports with *neighborProtocolVersion* [item j) in 35.2.1.4] of 0x00 shall use only the original Attribute Type (35.2.2.4) of Listener. Ports with *neighborProtocolVersion* of 0x01 or higher shall use either the original Attribute Type or the enhanced Attribute Type of Listener Enhanced.

In order to propagate an enhanced Attribute Type (e.g., registered from a Port with *neighborProtocolVersion* of 0x01) to an original Attribute Type (e.g., declared to a Port with *neighborProtocolVersion* of 0x00), fields of the attribute's FirstValue shall be translated as specified in Table 35-16.

NOTE—Original Attribute Types always propagate without translation, even if neighborProtocolVersion is 0x01 or higher.

Table 35-16—Translation of Listener attributes

Enhanced field	Original field	Enhanced to original translation
StreamID, MacAddress	StreamID, MAC Address	No change: This field determines the original Attribute Type to declare (Talker Advertise or Talker Failed).
StreamID, UniqueID	StreamID, Unique ID	No change: This field determines the original Attribute Type to declare (Talker Advertise or Talker Failed).
EndStationInterfaces	—	Not propagated: This TLV is not propagated through MAP, so translation is not applicable.
UserToNetworkRequirements, NumSeamlessTrees	—	Lost: If this field is not one, a Listener Ready or Listener Ready Failed declaration is converted to a Listener Asking Failed declaration.
UserToNetworkRequirements, MaxLatency	—	Lost: If this field is not zero, a Listener Ready or Listener Ready Failed declaration is converted to a Listener Asking Failed declaration.
InterfaceCapabilities	—	Not propagated: This TLV is not propagated through MAP, so translation is not applicable.
StatusInfo, TalkerStatus	—	No change: This field is set according to the TalkerStatus that the Bridge last propagated in the Talker attribute of the Stream. If no Talker attribute has been propagated, this field is set to zero (None).
StatusInfo, ListenerStatus	—	No change: This field determines the original FourPackedType (35.2.2.10) to declare.
StatusInfo, FailureCode	—	Lost: The declaration type does not change (i.e., fail).
InterfaceConfiguration	—	Not propagated: This TLV is not propagated through MAP, so translation is not applicable.

35.2.4.4.5 Merge MaxLatency

When more than one Listener provides the UserToNetworkRequirements TLV, multiple values of MaxLatency shall be merged by using the largest MaxLatency value in that set of multiple values. This ensures that Bridges closer to the Talker support the most flexible requirement for any Listener. The requirements of an individual Listener continue to be met in Bridges closer to that Listener.

35.2.4.4.6 Merge Listener Failures

As specified in 35.2.4.4.3, it is possible for a Bridge to merge failed Declaration Types for Listeners (e.g., Ready Failed with Asking Failed). Each failed Declaration Type uses a nonzero FailureCode (35.2.2.10.9) and a FailedInterfaces TLV associated with that FailureCode.

When merging failures, the FailedInterfaces TLV shall always be transferred with its corresponding StatusInfo TLV since the FailureCode is associated with the FailedInterfaces.

When merging a Ready Failed declaration with an Asking Failed declaration, the StatusInfo and FailedInterfaces shall be transferred from the Asking Failed declaration. When merging failed declarations with the same Declaration Type, the StatusInfo and FailedInterfaces shall be transferred from the declaration with the Failure Code of the lowest numeric value. When merging failed declarations with the same Declaration Type and Failure Code, the decision of which failure to transfer is left to the Bridge's implementation.

35.2.4.5 MAP Context for MSRP

MSRPDUs can carry information about Streams in multiple VLANs, which in an MST environment, can be in different spanning tree instances. Queue resources, however, are allocated and used according to priority parameters, not according to VID. Furthermore, on a shared medium, Streams can use the shared medium even on VLANs that are blocked on the Bridge's Port to that shared medium (e.g., consider an IEEE 802.11 AP that transmits frames between two stations that are on a VLAN that is blocked on the AP). Therefore, there is a single context for MSRP Attribute Propagation that includes all Bridge Ports. The Declarations are filtered according to the requirements of 35.2.4 and its subclauses and according to the state of the spanning tree per 35.1.3.1.

All MSRPDUs are transmitted as untagged frames.

35.2.4.6 MaxLatency Comparison

The comparison for UserToNetworkRequirements.MaxLatency greater than zero determines whether to fail the Stream due to AccumulatedLatency (35.2.2.8.6, 35.2.2.10.10) that exceeds the requirement specified by Talkers and/or Listeners. The comparison is performed separately for the Talker and each Listener.

For the Talker, the UserToNetworkRequirements.MaxLatency from the Talker is compared to AccumulatedLatency for all Listeners of the Stream. For example, if the Bridge forwards the Stream to three Ports (three Listeners registered), the Talker's UserToNetworkRequirements.MaxLatency is compared to three values of AccumulatedLatency. For any of the comparisons, if any Listener's AccumulatedLatency is greater than the Talker's UserToNetworkRequirements.MaxLatency, the Talker fails the MaxLatency comparison.

If the Talker fails the MaxLatency comparison and the Declaration Type of the Talker is Advertise, the Bridge shall change Talker Advertise to Talker Failed and report Failure Code=21 (Table 46-15).

For the Listener, the UserToNetworkRequirements.MaxLatency from the Listener is compared to AccumulatedLatency for the corresponding Listener. If the Listener's AccumulatedLatency is greater than the Listener's UserToNetworkRequirements.MaxLatency, the Listener fails the MaxLatency comparison.

If the Listener fails the MaxLatency comparison, the Bridge shall change Listener Ready to Listener Asking Failed for the failed Listener and report Failure Code=21. The Listener Asking Failed is merged with declarations of other Listeners to determine the resultant Declaration Type to the Talker (35.2.4.4.3).

In the fully distributed model (46.1.3.1), the comparison for the Talker's UserToNetworkRequirements.MaxLatency is performed in each Bridge in the path from the Talker to each Listener, in the same direction as AccumulatedLatency. In the fully distributed model, the comparison for the Listener's UserToNetworkRequirements.MaxLatency is performed in each Bridge in the path from the Listener to each Talker, using the AccumulatedLatency from the Talker's attribute.

In the centralized network/distributed user model (46.1.3.2), the comparison for the Talker's and Listener's UserToNetworkRequirements.MaxLatency is performed in the CNC, using the capabilities of each Bridge as learned through remote management (e.g., Bridge Delay of 12.32.1). When the CNC detects failure of the MaxLatency comparison, Failure Code 21 is declared to the Talker and Listener as specified in item a) in 35.2.2.10.

35.2.5 Operational reporting and statistics

35.2.5.1 Dropped Stream Frame Counter

An implementation may support the ability to maintain a per-port per-traffic class count of data stream frames that are dropped for any reason. These are not MRP frames, but the data stream frames that flow between Talker and Listener(s) through the reservations established by MSRP.

35.2.6 Encoding

If an MSRP message is received from a Port with an event value specifying the JoinIn or JoinMt message, and if the StreamID (35.2.2.8.2, 35.2.2.10.2), and Direction (35.2.1.2) all match those of an attribute already registered on that Port, and the Attribute Type (35.2.2.4) or FourPackedEvent (35.2.2.7.2) has changed, then the Bridge should behave as though an **rLv!** event (with immediate leavetimer expiration in the Registrar state table) was generated for the MAD in the Received MSRP Attribute Declarations before the **rJoinIn!** or **rJoinMt!** event for the attribute in the received message is processed. This allows an Applicant to indicate a change in a stream reservation, e.g., a change from a Talker Failed to a Talker Advertise registration, without having to issue both a withdrawal of the old attribute, and a declaration of the new. A Listener attribute is also updated this way, for example, when changing from a Listener Ready to a Listener Ready Failed.

NOTE—This rule ensures that there is at most one Listener Declaration or one Talker Declaration for any given value of StreamID on any given port. In the unlikely situation where a Talker Advertise and a Talker Failed are received for the same Stream on the same port, the Talker Failed declaration takes precedence.

The following examples will help clarify the intent of this subclause. The first example describes the behavior when one attribute (Talker Advertise) is replaced by another (Talker Failed). The second example describes the behavior when the MSRP FourPackedEvents changes with a single Listener attribute.

This example illustrates processing of Talker Declaration changes. Assume a Bridge is receiving Talker Advertise declarations on an inbound Port. An emergency situation occurs and a 911 call is being placed via an entirely different Stream. The bandwidth that was available for the first Stream is now no longer available so the Bridge begins receiving Talker Failed declarations for that original stream. The MAP function realizes the Talker declaration has changed for the Stream and generates an internal leave event for the Talker Advertise and a join event for the Talker Failed. This behavior guarantees there will not be a declaration for a Talker Advertise and a Talker Failed for a single Stream existing within the Bridge at the same time.

As another example assume the same situation has occurred as described in the example above (a 911 call). For this scenario consider the Listener declarations flowing in the opposite direction. When there was bandwidth available the Bridge was declaring a Listener Ready, which was then changed to a Listener Asking Failed as soon as the 911 call came through. The other Bridge receiving these Listener declarations

realized that the Listener attribute MSRP FourPackedEvents had changed and acted as if the Listener declaration had been withdrawn and replaced by the updated Listener declaration.

35.2.7 Attribute value support requirements

Implementations of MSRP shall maintain state information for all attribute values that support the Stream registrations (35.2.2.8, 35.2.2.10).

Implementations of MSRP shall be capable of supporting any attribute value in the range of possible values that can be registered using Stream registrations; however, the maximum number of attribute values for which the implementation is able to maintain current state information is an implementation decision, and may be different for Talker attributes and Listener attributes. The number of values that the implementation can support shall be stated in the PICS.

36. Priority-based Flow Control (PFC)

This clause specifies the operation of PFC (see 36.1) and the architecture of Priority-based Flow Control in a PFC-aware system (see 36.2).

The models of operation in this clause provide a basis for specifying the externally observable behavior of PFC and are not intended to place additional constraints on implementations; these can adopt any internal model of operation compatible with the externally observable behavior specified.

36.1 PFC operation

36.1.1 Overview

Operation of PFC is limited to a data center environment. PFC enables to not discard frames due to congestion for protocols that require this property. However, PFC can cause congestion spreading behavior; therefore, it is intended for use on networks of limited extent. When PFC is used, deployment of congestion notification (see Clause 30) can reduce the frequency with which PFC is invoked.

PFC is a function defined only for a pair of full duplex MACs (e.g., IEEE 802.3 MACs operating in point-to-point full-duplex mode) connected by one point-to-point link. Use of PFC on shared media such as EPON is out of the scope of this standard. Figure 36-1 shows an example of PFC peering when IEEE 802.3 point-to-point full-duplex MACs are used.

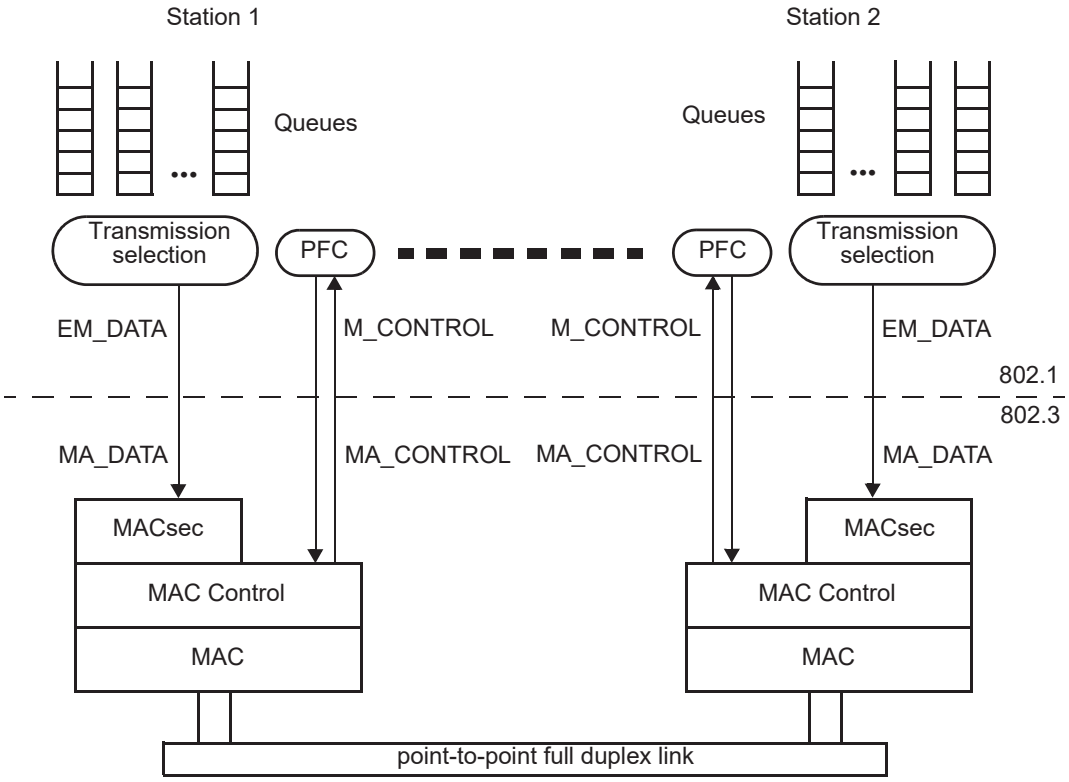

Figure 36-1—PFC peering

PFC allows link flow control to be performed on a per-priority basis. In particular, PFC is used to inhibit transmission of data frames associated with one or more priorities for a specified period of time. PFC can be enabled for some priorities on the link and disabled for others.

Given that BPDUs, for example, are sent untagged and can bypass the output queues, it is strongly recommended for the default priority of a port to not have PFC enabled.

NOTE—The LLC-SAP of a Bridge Port can host a management protocol stack that uses PFC-enabled priorities, and these management frames can bypass the output queues. In this situation PFC can fail to provide insurance against these frames overflowing the buffer in the remote station of the link.

36.1.2 PFC primitives

PFC is invoked through the M_CONTROL PFC primitives (11.4 of IEEE Std 802.1AC-2016 [B8]). A system client wishing to inhibit transmission of data frames on certain priorities from the remote system on the link generates an M_CONTROL.request primitive specifying the following:

a) The globally assigned 48-bit multicast address 01-80-C2-00-00-01.
b) The PFC opcode (i.e., 01-01).
c) A request_operand_list with two operands indicating, respectively, the set of priorities addressed and the lengths of time for which it wishes to inhibit data frame transmission of the corresponding priorities.

NOTE—By definition, a point-to-point full-duplex link comprises exactly two stations, thus there is no ambiguity regarding the destination station's identity. The use of a well-known multicast address does not require a station to know, and maintain knowledge of, the individual 48-bit address of the other station.

As specified in IEEE Std 802.3, when PFC is enabled on a port for at least one priority over an IEEE 802.3 link layer, the IEEE Std 802.3 PAUSE mechanism is not used for that port.

As a result of the processing of the PFC M_CONTROL.request, the peering PFC station receives a PFC M_CONTROL.indication primitive.

The parameters of the PFC M_CONTROL.indication are as follows:

d) The PFC opcode (i.e., 01-01).
e) A indication_operand_list with two operands indicating, respectively, the set of priorities addressed and the lengths of time for which data frame transmission of the corresponding priorities has to be inhibited.

The request_operand_list of a PFC M_CONTROL.request and the indication_operand_list of a PFC M_CONTROL.indication are composed of the following operands:

f) priority_enable_vector: a 2-octet field, with the most significant octet being reserved (i.e., set to zero on transmission and ignored on receipt). Each bit of the least significant octet indicates if the corresponding field in the time_vector parameter is valid. The bits of the least significant octet are named e[0] (the LSB) to e[7] (the MSB). Bit e[n] refers to priority n. For each e[n] bit set to one, the corresponding time[n] value is valid. For each e[n] bit set to zero, the corresponding time[n] value is invalid.
g) time_vector: a list of eight 2-octet fields, named time[0] to time[7]. The eight time[n] values are always present regardless of the value of the corresponding e[n] bit. Each time[n] field is a 2-octet, unsigned integer containing the length of time for which the receiving station is requested to inhibit transmission of data frames associated with priority n. The field is transmitted most significant octet first, and least significant octet second. The time[n] fields are transmitted sequentially, with time[0] transmitted first and time[7] transmitted last. Each time[n] value is measured in units of pause_quanta, equal to the time required to transmit 512 bits of a frame at the data rate of the MAC. Each time[n] field can assume a value in the range of 0 to 65 535 pause_quanta.

36.1.3 Detailed specification of PFC operation

36.1.3.1 Processing PFC M_CONTROL.requests

Invoking the PFC M_CONTROL.request results in the invocation of the appropriate link layer service request. For IEEE 802.3 link layers the PFC M_CONTROL.request is mapped to a PFC MA_CONTROL.request (IEEE Std 802.1AC). If PFC is not enabled for priority n, then PFC requests with e[n] set to one and time[n] different than zero (see 36.1.2) should not be generated.

NOTE—In the IEEE 802.1Q architecture frames coming from the LLC, including BPDUs, bypass the priority queues and therefore are not subject to PFC. However, in some implementations frames coming from the LLC can pass through the priority queues. In this case, it is not recommended to enable PFC for the priority to which BPDUs are assigned (usually priority 7).

36.1.3.2 Processing PFC M_CONTROL.indications

The PFC Receiver entity (see 36.2.2) maintains and makes available to Transmission Selection the vector of the Priority_Paused[n] variables, indicating the state of each of the eight priorities. Each Priority_Paused[n] variable is a boolean. When Priority_Paused[n] is FALSE, priority n is not in paused state. When Priority_Paused[n] is TRUE, priority n is in paused state.

Figure 36-2 shows the PFC state diagram for priority n. If PFC is not enabled for priority n, then the PFC state diagram does not apply to priority n and Priority_Paused[n] is FALSE.

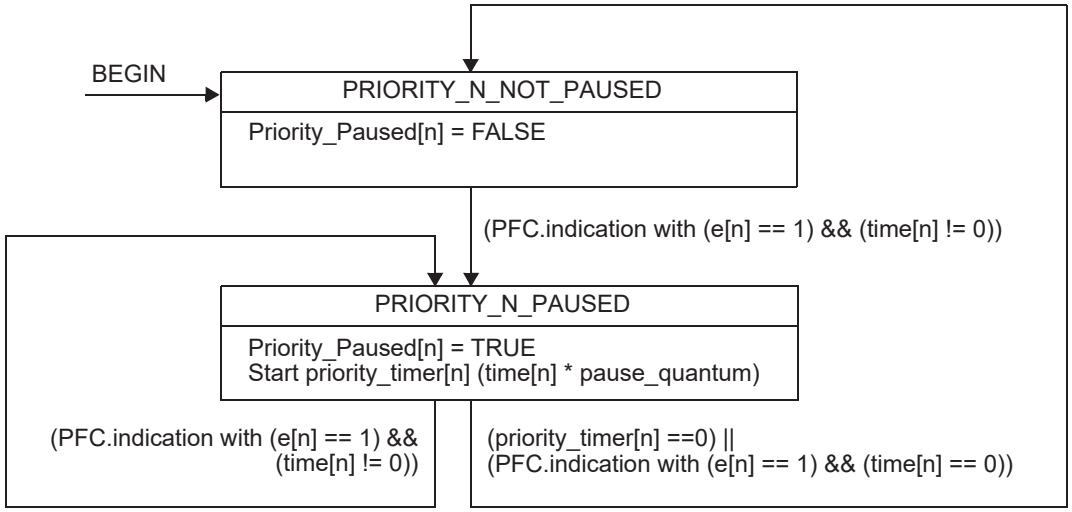

Figure 36-2—PFC Receiver state diagram for priority n

Upon receipt of a PFC M_CONTROL.indication, the PFC Receiver programs up to eight separate timers, each associated with a different priority, depending on the priority_enable_vector. For each bit in the priority_enable_vector that is set to one, the corresponding timer value is set to the corresponding time value in the time_vector parameter. Priority_Paused[n] is set to TRUE when the corresponding timer value (i.e., priority_timer[n]) is nonzero. Priority_Paused[n] is set to FALSE when the corresponding timer value (i.e., priority_timer[n]) counts down to zero. A time value of zero in the time_vector parameter has the same effect as the timer having counted down to zero. If PFC is not enabled for priority n and a PFC indication is received with e[n] set to one, then the time[n] parameter is ignored (i.e., the primitive is processed as if e[n] was set to zero).

NOTE—A priority_enable_vector with all bits set to zero is legal and equivalent to a no-op.

36.1.3.3 Timing considerations

For effective flow control on a point-to-point full-duplex link, it is necessary to place an upper bound on the length of time that a device can transmit data frames after receiving a PFC M_CONTROL.indication with e[n] set to one in the priority_enable_vector and a nonzero time[n] in the time_vector operands.

If MACsec is not supported, a queue shall go into paused state in no more than 614.4 ns since the reception of a PFC M_CONTROL.indication that paused that priority. This delay is equivalent to 12 pause quanta (i.e., 6144 bit times) at the speed of 10 Gb/s, 48 pause quanta (i.e., 24 576 bit times) at the speed of 40 Gb/s, and 120 pause quanta (i.e., 61 440 bit times) at the speed of 100 Gb/s.

If MACsec is used, a queue shall go into paused state in no more than 614.4 ns + 'SecY transmit delay' (see IEEE Std 802.1AE) since the reception of a PFC M_CONTROL.indication that paused that priority. The 'SecY transmit delay' is defined as the wire transmit time for a maximum sized MPDU + 4 times the wire transmit time for 64 octet MPDUs. For a 2000-byte frame the 'SecY transmit delay' is $8 \times (2000 + 20) + 8 \times 4 \times (64 + 12 + 4 + 20) = 19\,360$ bit times.

NOTE 1—19 360 bit times is an appropriate value for 'SecY transmit delay' for speeds up to 10 Gb/s. Support for the speeds of 40 Gb/s and 100 Gb/s can require a higher value.

If MACsec is supported but not used, the delay computation has to take into account the MACsec Bypass Capability (MBC) bit in the PFC configuration TLV of DCBX (D.2.10), that indicates if the link peer needs the extra time for MACsec. If the MBC bit is set to zero, the maximum PFC delay is 614.4 ns. If the MBC bit is set to one, the maximum PFC delay is 614.4 ns + 'SecY transmit delay'.

NOTE 2—In addition to the above delays, system designers should take into account the delay of the PHY and of the link segment when designing devices that implement the PFC operation to ensure frames are not lost due to congestion (see Annex O for additional discussion on this topic).

36.2 PFC-aware system queue functions

Figure 36-3 illustrates the architecture of the queue functions of a PFC-aware system when Link Aggregation is not used. These functions offer a service to higher layers that utilizes a single instance of the ISS or EISS to connect to the lower layers. In Figure 36-3, two major blocks are outlined with dotted boundaries:

a) The PFC Initiator block, in the right of Figure 36-3 (see 36.2.1)
b) The outbound queue block, in the left of Figure 36-3 (see Figure 22-2)

The remaining entities illustrated in Figure 36-3, other than the PFC Receiver entity, are part of the IEEE 802.1 architecture and are not further discussed here.

36.2.1 PFC Initiator

The PFC Initiator entity generates M_CONTROL PFC requests using the M_CONTROL.request primitive (see 36.1.3.1) when appropriate (e.g., when an input buffer reaches a certain threshold).

36.2.2 PFC Receiver

The PFC Receiver entity processes the M_CONTROL.indication primitives as specified in 36.1.3.2. In addition, the PFC Receiver maintains and makes available to Transmission Selection the vector of the Priority_Paused[n] variables, indicating the state of each of the eight priorities.

The PFC Receiver entity acts per physical port. When Transmission Selection is running above Link Aggregation, each PFC Receiver entity processes the M_CONTROL.indication primitives as specified in 36.1.3.2, and maintains and makes available to Transmission Selection the vector of the Priority_Paused[n]

variables, indicating the state of each of the eight priorities of that physical link, as shown in Figure 36-4.

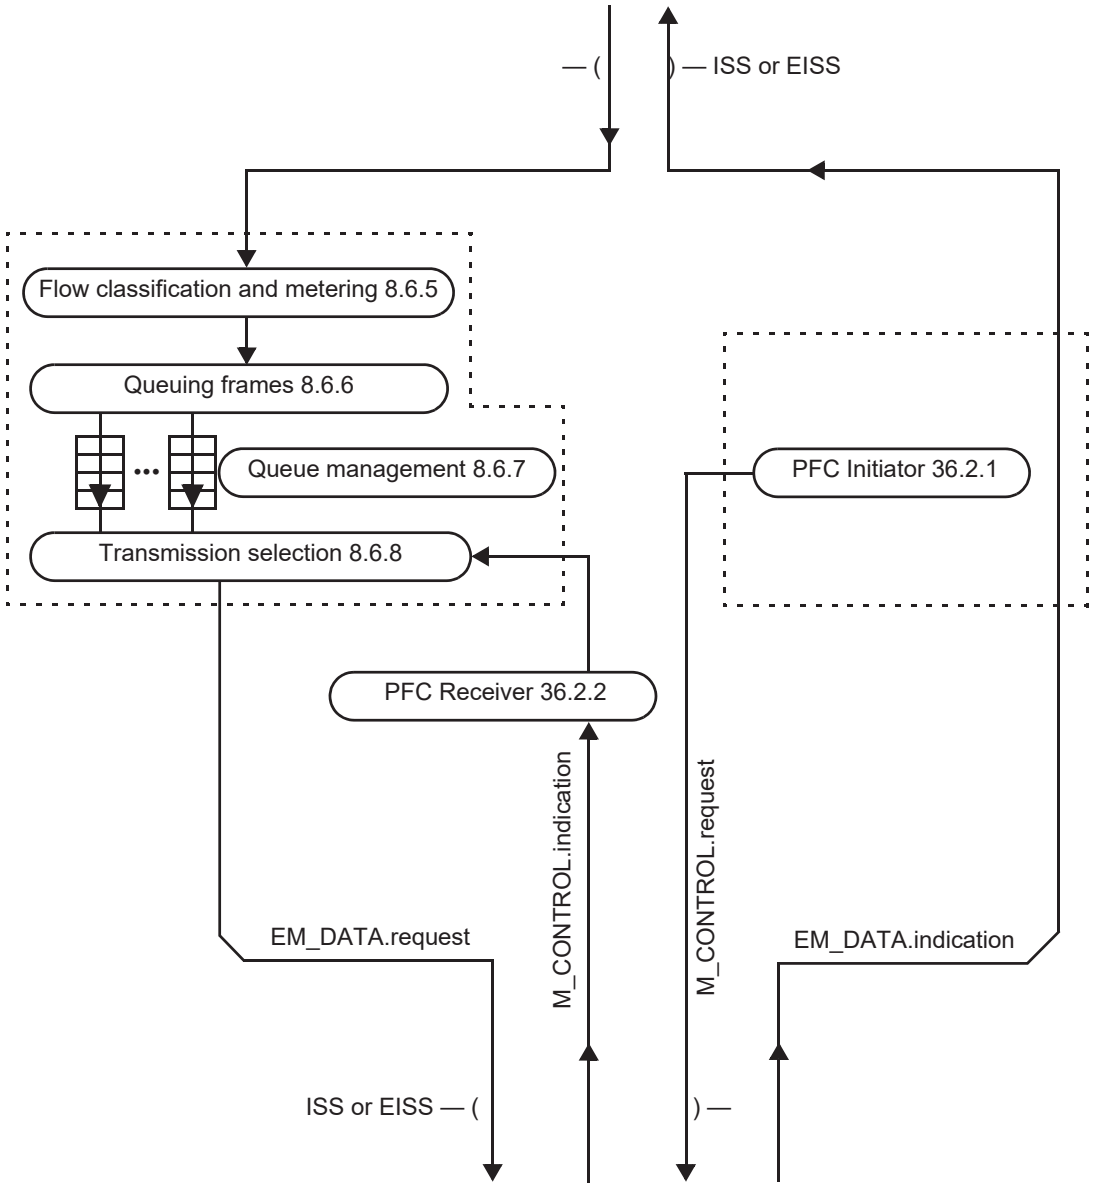

Figure 36-3—PFC-aware system queue functions

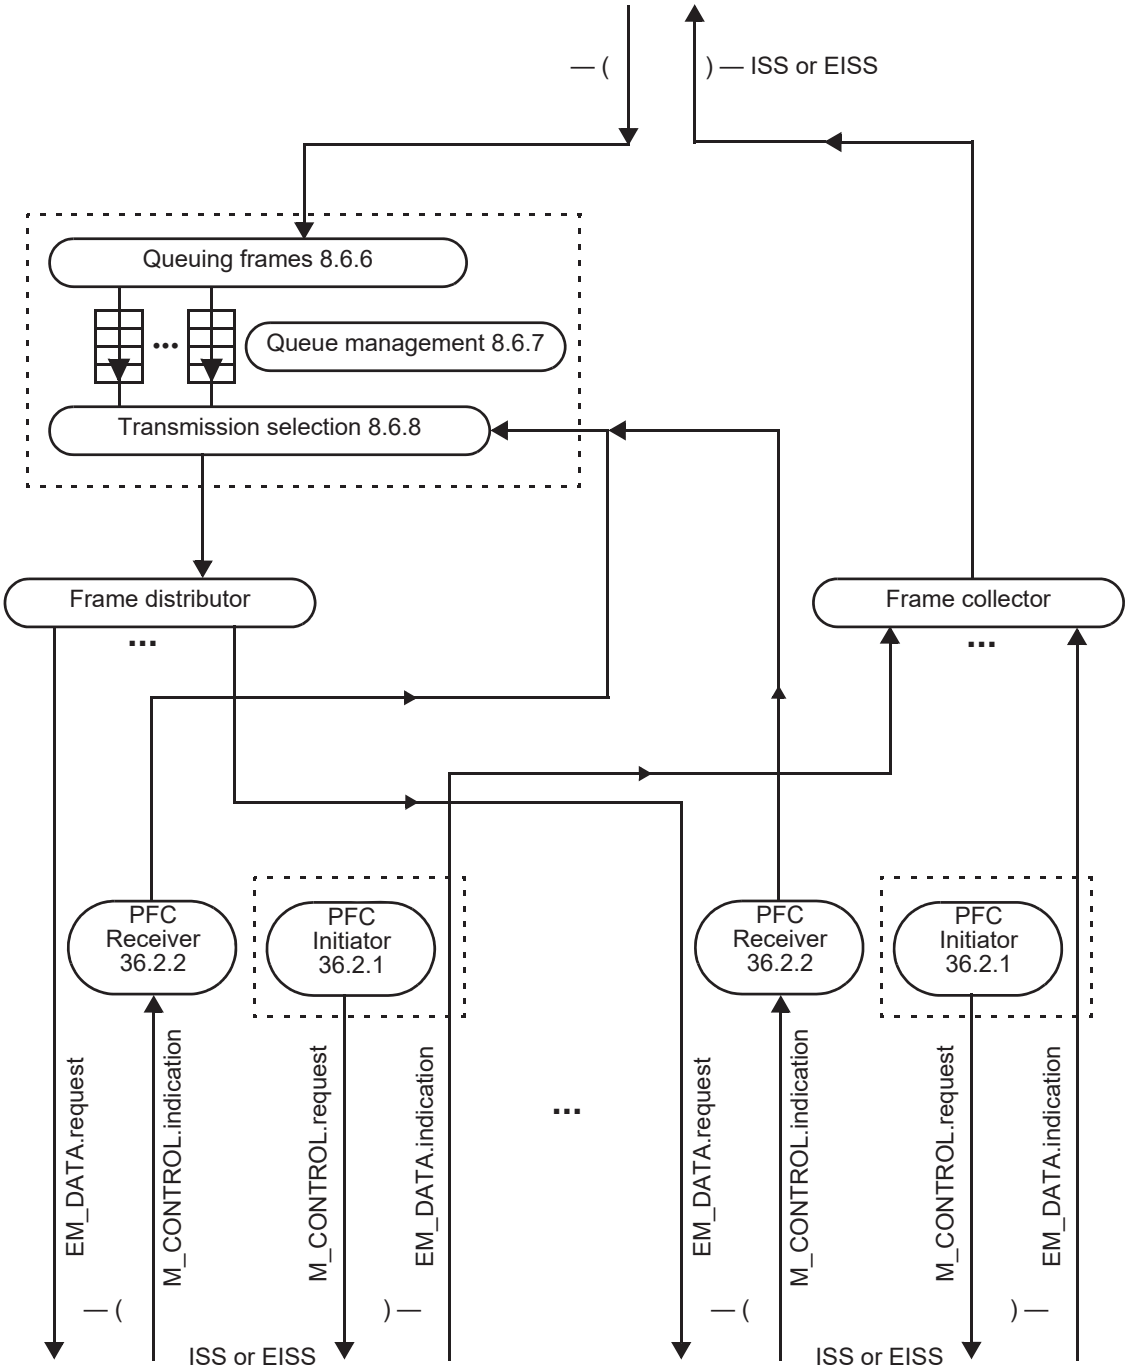

Figure 36-4—PFC-aware system queue functions with Link Aggregation

37. Enhanced Transmission Selection (ETS)

37.1 Overview

This clause provides definitions and an operational model for priority processing and bandwidth allocation in end stations and Bridges in a Data Center Bridging (DCB) environment. Using Priority-based processing and bandwidth allocations, different traffic classes with different types of traffic such as LAN, Storage Networking, Clustering, and management can be configured to provide bandwidth allocation, or best effort transmit characteristics.

In order to accomplish this, the following are provided:

a) A set of bandwidth configuration parameters that are used to configure the percentage of bandwidth assigned to each traffic class.
b) A set of characteristics that an ETS enabled transmitter is required to follow.
c) A means of communicating priority-to-traffic class allocations to neighboring systems (DCBX; see Clause 38).

37.1.1 Relationship to other transmission selection algorithms

If ETS is used in conjunction with the strict priority and credit-based shaper algorithms, then attention should be paid to assignment of traffic classes as specified in 34.5.

37.2 ETS configuration parameters

The following ETS configuration parameters exist for each ETS enabled port:

a) *numTrafficClassesSupported*: Indicates the number of traffic classes supported by a port. This value has a minimum of 3 (see 37.3) and a maximum of 8.
b) *TCPriorityAssignment(P)*: For each supported priority, P, the traffic class to which that priority P is assigned (see 37.1.1). A traffic class only operates with the ETS algorithm if it is assigned to do so by the Transmission Selection Algorithm Table (see 8.6.8); i.e., the entry in the table for that traffic class is assigned the value 2 (see Table 8-6).
c) *TCBandwidth(N)*: For each traffic class N, the percentage of the available bandwidth assigned to that traffic class. The total for all traffic classes is equal to 100% (see 37.3).

Configuration of ETS parameters shall be done via DCBX (see Clause 38).

37.3 ETS algorithm

The ETS algorithm provides allocation of bandwidth to traffic classes. The algorithm allows bandwidth intensive and loss sensitive traffic to share the network while allowing coexistence with low latency traffic using the strict priority and credit-based shaper algorithms. Since there are a number of variants of bandwidth sharing algorithms (such as weighted round robin) that provide appropriate bandwidth sharing, a detailed algorithm is not specified. Any algorithm is allowed as long as it meets the specified performance requirements.

NOTE 1—The ETS algorithm is used to determine when an ETS traffic class has a frame available to transmit. The determination of which frame in the traffic class to send can be done in an implementation specific manner, subject to the ordering requirements in 8.6.6.

For the purposes of the ETS algorithm, Available Bandwidth is defined as the link bandwidth remaining after traffic classes not assigned to Transmission selection algorithm 2, and Vendor Specific (see Table 8-6)

are serviced. The effect of Vendor Specific algorithms to Available Bandwidth is outside the scope of this standard.

The ETS algorithm shall provide the ability to configure traffic classes to share bandwidth according to the following:

a) Allow one or more priorities to be assigned to a traffic class.

   NOTE 2—All priorities within a traffic class typically share similar traffic handling requirements (e.g., loss and bandwidth).

b) Allow bandwidth to be configured for each traffic class with a granularity of 1%. The configured bandwidth indicates the percentage of Available Bandwidth that can be used by the traffic class when all other traffic classes are consuming their configured bandwidth.

c) For traffic classes for which the transmission selection algorithm is ETS (i.e., Transmission selection algorithm 2 in Table 8-6), select frames for transmission from the traffic class queues such that the bandwidth consumed by the traffic class approaches its percentage of Available Bandwidth. The traffic class consumes less than its percentage of Available Bandwidth when the offered load for that traffic class is less than its percentage of Available Bandwidth, in that case the remainder of its percentage of Available Bandwidth can be used by other traffic classes. A traffic class can consume more than its percentage of Available Bandwidth when the offered load of other traffic classes results in those traffic classes consuming less than their percentage of Available Bandwidth. Allocation of any excess Available Bandwidth is implementation specific.

d) When all traffic classes are offered enough load to consume their share of available bandwidth, and there is no offered load in the traffic classes using transmission selection algorithms other than ETS, the bandwidth received from an ETS traffic class shall deviate from its allocation by no more than 10% of the available bandwidth when measured over a period of 10 000 000 bit times using maximum sized frames during a time period when no PFC frames are received (i.e., no congestion).

   NOTE 3—The measurement window is derived from an approximate number of bits in 500 frames (i.e., 500 frames × 2000 bytes per frame × 8 bits per byte rounded up to 10 000 000).

   NOTE 4—Allowed deviation of ± 10% allows for variations of traffic (e.g., burstiness) over the specified measurement window and provides balance between precision and implementation flexibility.

e) At least 3 traffic classes shall be supported per port. A minimum of 3 traffic classes allows a minimum configuration such that one ETS traffic class contains priorities that have PFC enabled, one ETS traffic class contains priorities that have PFC disabled, and one traffic class using strict priority.

37.4 Legacy configuration

Subclause 8.6.8 specifies strict priority scheduling as default behavior. This can be achieved by configuring the Transmission selection algorithm value for a traffic class to 0 (see Table 8-6).

Subclause 8.6.6 specifies the default priority to traffic class mapping. There is no change to such mapping when ETS is used.

38. Data Center Bridging eXchange protocol (DCBX)

38.1 Overview

This clause details the DCBX, which is used by DCB devices to exchange configuration information with directly connected peers. The protocol may also be used for misconfiguration detection and for configuration of the peer.

This standard describes the base protocol, which comprises state machines and TLVs for capability exchange. For each feature that is supported by DCBX, the attributes that are to be exchanged specify the following:

a) The attributes to be exchanged
b) How the attributes are used for detecting misconfiguration
c) What action needs to be taken when a misconfiguration is detected

The information listed above is specified for the following:

d) ETS
e) PFC
f) Application Priority TLV
g) Application VLAN TLV

38.2 Goals

The goals of DCBX are as follows:

a) Discovery of DCB capability in a peer port; for example, it can be used to determine if two link peer ports support PFC.
b) DCB feature misconfiguration detection: DCBX can be used to detect misconfiguration of a feature between the peers on a link. Misconfiguration detection is feature-specific because some features allow asymmetric configuration.
c) Peer configuration of DCB features: DCBX can be used by a device to perform configuration of DCB features in its peer port if the peer port is willing to accept configuration.

38.3 Types of DCBX attributes

Three types of DCBX attributes are exchanged:

a) Informational attributes (see 38.3.1)
b) Asymmetric attributes (see 38.4.1)
c) Symmetric attributes (see 38.4.2)

38.3.1 Informational attributes

Informational attributes are exchanged via LLDP without any participation in a DCBX state machine.

38.4 DCBX and LLDP

DCBX uses Link Layer Discovery Protocol (LLDP) (see IEEE Std 802.1AB) to exchange attributes between two link peers. LLDP is a unidirectional protocol. It advertises connectivity and management information about the local station to adjacent stations on the same IEEE 802 LAN.

DCB exchanged attributes are packaged into Organizationally Specific TLVs. The OUI used for the DCBX TLV is the IEEE 802.1 OUI (i.e, 00-80-C2).

DCBX state machine transitions are based on the DCBX objects in the LLDP MIB module. Operation of the DCBX state machine may affect the values of the DCBX objects in the LLDP MIB module.

A port capable of any DCB feature shall have the capability for DCBX to be administratively disabled. The default state for DCBX is enabled.

DCBX is expected to operate over a point-to-point link. If multiple LLDP peer ports running DCBX are detected, then DCBX should behave as if the peer port's DCBX TLVs are not present until the multiple LLDP peer port condition is no longer present. However, a transition in LLDP peer port may occur in some circumstances (e.g., such as a transition from system boot to system operation). Therefore, when it is detected that the number of peer ports running DCBX exceeds 1 for a period longer than the longest TTL of any of the peers, a multi-peer condition is detected. During the time when the multi-peer condition has not been detected the DCBX data from the most recent DCBX peer shall be used. An LLDP peer port is identified by a concatenation of the chassis ID and port ID values transmitted in the LLDPDU. A DCBX peer port is a LLDP peer port that is sending DCBX TLVs.

DCBX defines two different types of attribute passing mechanisms:

a) Asymmetric: the passing of a attribute from one port to its peer port. In this case, the desired configuration for the peer may not match the local configuration.
b) Symmetric: the passing of a attribute from one port to its peer port with objective of both ports utilizing the same attribute value.

38.4.1 Asymmetric attribute passing

38.4.1.1 Overview

Two types of TLV are passed for Asymmetric attribute Passing:

a) Configuration TLV: Provides current operational state and Willing bit. The received Willing bit is not used by the state machine, but instead provided to higher layers to provide an indication of the expected behavior of the remote port. The presence of the willing bit set to 1 indicates to the remote port that the local port is willing to accept a configuration for the specific attribute for which the willing bit is set.
b) Recommendation TLV: Provides recommendation for the operational state of remote port. Transmitted only if the local port is configured to make recommendations in which case it is transmitted in all LLDPDUs. Transmitted regardless of the "willingness" of the remote port.

NOTE—An implementation is allowed to send a recommendation TLV or a configuration TLV or both.

38.4.1.2 Asymmetric state variables

LocalWilling: Indicates that the local port has been administratively configured to accept recommendations. This value is included in the Willing bit of Configuration TLVs transmitted by this port. A local port may be configured as not Willing.

OperParam: The current operational value of the attribute on the local port. This value is included as the attribute in the Configuration TLVs.

LocalAdminParam: The administratively configured value for the attribute. This becomes the operational value of the attribute by default, and the operational value may be overridden if the local port accepts a recommendation from the remote port.

RemoteParam: The attribute received in the last Recommendation TLV. This variable is set to NULL if the remote LLDP database contains no Recommendation TLV.

DCBXMapping: A function that maps the received parameters to the capabilities of the receiving port.

38.4.1.3 Asymmetric state machine

The Asymmetric state machine is depicted in Figure 38-1.

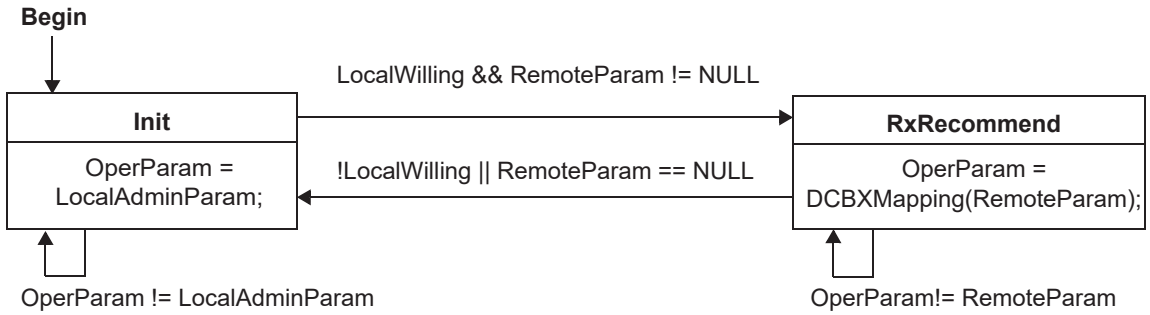

Figure 38-1—DCBX Asymmetric state machine

38.4.2 Symmetric attribute passing

38.4.2.1 Overview

For Symmetric attribute passing one type of TLV is used:

a) Configuration TLV. This TLV always carries the current local operational state and a Willing (W) bit.

A port that sets the W bit is considered Willing. A Willing port shall set its operational attribute to that indicated in the received TLV if the received TLV has the W bit set to zero. If both the local port and remote port are willing, then the attribute values of the port with the lower numerical MAC address shall take precedence.

38.4.2.2 Symmetric state variables

LocalWilling: Indicates that the local port has been administratively configured to accept the attribute from the remote port. This value is included in the Willing bit of DCBX TLVs transmitted by this port.

RemoteWilling: rwTrue indicates that the Willing bit was set in the last TLV received. rwFalse indicates that the Willing bit was not set in the last TLV received. This variable is set to rwNull if the remote LLDP database contains no Willing bit.

LocalMAC: The MAC address of the local port.

RemoteMAC: The MAC address of the remote port.

OperParam: The current operational value of the attribute on the local port. This value is included as the attribute in the DCBX TLV.

RemoteParam: Contains the value of the last attribute (i.e., the operational value of the remote port) received in the TLV. This variable is set to NULL if the remote LLDP database contains no TLV.

LocalAdminParam: The administratively configured value for the attribute. This becomes the operational value of the attribute by default, and may be overridden if the local port accepts the attribute from the remote port.

DCBXMapping: A function that maps the received parameters to the capabilities of the receiving port.

38.4.2.3 Symmetric state machine

The Symmetric state machine is depicted in Figure 38-2.

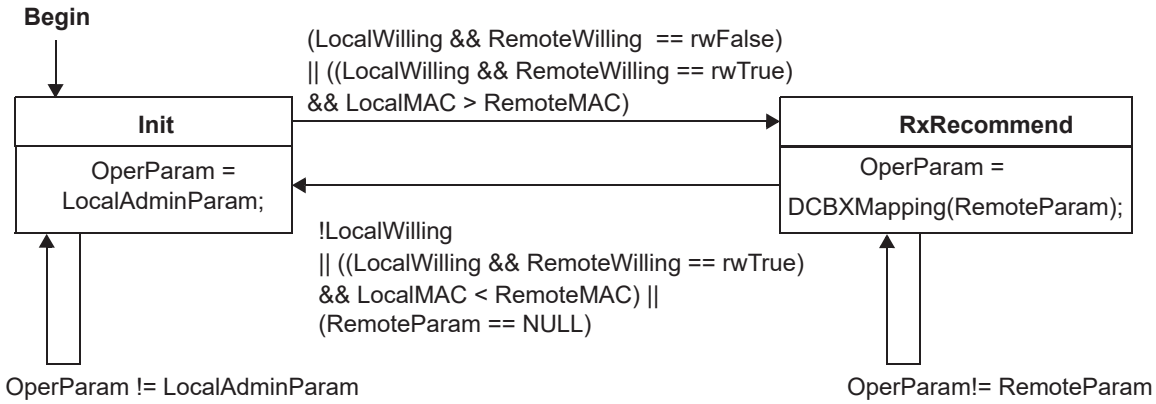

Figure 38-2—Symmetric state machine

NOTE—Through observation of the states and state variables it is possible to determine that the state machine is in the process of passing attributes. This knowledge may be useful for clients of DCBX. For example, a client may wish to delay use of the link while the DCBX state machine is in the process of passing and possibly setting attributes. A "Pending" indication indicating that the state machine is in this process may be created by the following equations:

```
Pending = RemoteParam == NULL
|| !LocalWilling && RemoteWilling == rwTrue && OperParam != RemoteParam;
```

39. Multiple I-SID Registration Protocol (MIRP)

MIRP defines an MRP application (10.1) that provides the ability to flush learned MAC Address Entries held in the FDB of an I-component on a per-I-SID basis. MIRP makes use of MRP Attribute Declaration (MAD) and MRP Attribute Propagation (MAP), which provide the common state machine descriptions and the common attribute propagation mechanisms defined for use in MRP-based applications. The MRP architecture, MAD, and MAP are defined in Clause 10.

In a PBBN, the assignment of S-VIDs and I-SIDs to VIPs is often fixed, and the overhead of signaling the creation of Dynamic VLAN Registration Entries among I-components is undesirable. It can nevertheless be necessary to signal the need to flush the I-components' FDBs of learned MAC address information. For example, one could configure a point-to-point service that is dual-homed (has two I-components) at each end of the service, only two of which (one at each end) are active at any one time. A failure that causes one I-component to take over from the other requires that the active I-component at the other end of the service forget its associations of C-MAC addresses to the failed I-component's B-MAC address. Therefore, the MIRP application supports the Registration Fixed (New propagated), instead of the Registration Fixed (New ignored), value in the Registrar Administrative Controls.

The function of MIRP can be performed by MVRP. However, in an I-component with one S-VID per VIP requires 4094 MVRPDUs, one for each VIP, to signal a simultaneous topology change on all 4094 S-VIDs, whereas it can signal those same topology changes with a single Multiple I-SID Registration Protocol Data Unit (MIRPDU) through the PIP.

39.1 MIRP overview

MIRP is an extension of MVRP (11.2) for use in I-components and B-components. The extensions in both I-components and B-components are as follows:

a) The attribute values carried by the MIRPDUs are 24-bit I-SID values, rather than 12-bit VIDs in an MVRPDU.
b) A MIRP Participant can only be a New-Only Participant (10.6), so the Registrar Administrative Controls can take only the value, Registration Fixed (New propagated).
c) MIRP uses the Nearest Customer Bridge group address (Table 8-1) or the Default Backbone Destination from the CBP's Backbone Service Instance table (6.11) instead of an MRP Application address from Table 10-1, so a Provider Bridge forwards frames containing MIRPDUs normally, while a Customer Bridge filters them.

In an I-component only, the extensions are as follows:

d) A VIP in an I-component can be attached to an MVRP Participant or to a MIRP Participant, but not to both.
e) An MVRP to MIRP attributes translation function (39.2.1.1) enables interoperation between the MVRP and MIRP Participants in the I-component.
f) There is only one MIRP Participant and one instance of the MIRP application per PIP.

In a B-component only, the extensions are as follows:

g) MIRP Participants are placed on zero or more CBPs, and on at most one non-CBP Port in the B-component.
h) MAP (10.3) operates among MIRP MAD components only, using 24-bit MIRP I-SID values.

Figure 39-1 illustrates the architecture of MVRP and MIRP in an I-component. The arrows showing the relationship between the MVRP or MIRP applications and the FDB in the MAC Relay Entity have been omitted from Figure 39-1, but these relationships are the same as those shown in Figure 11-1.

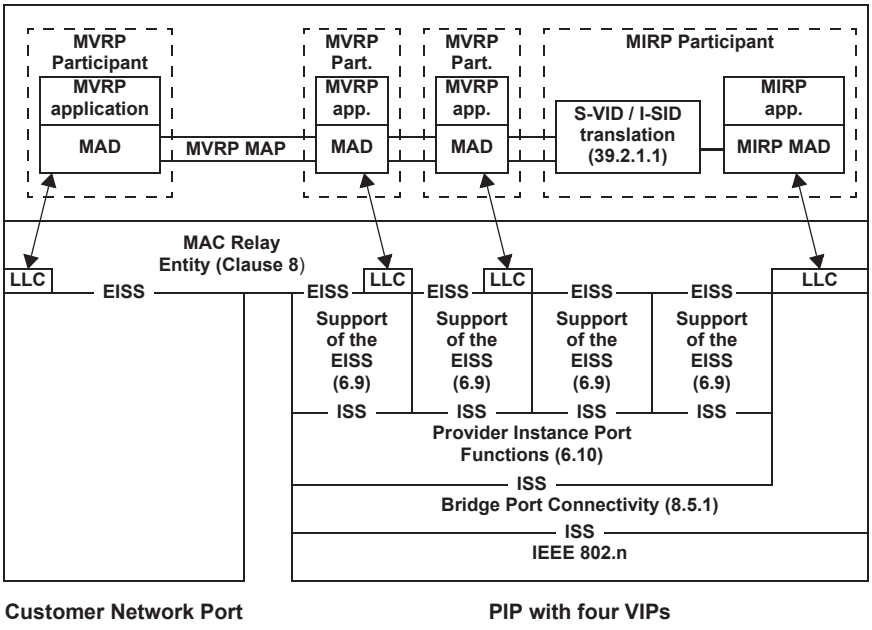

Figure 39-1—Operation of MIRP in an I-component

The architecture of MIRP in a B-component is illustrated in Figure 39-2. One management Port and one CBP are shown, although any number of CBPs can be supported. (See 39.2.2 for an alternate model.)

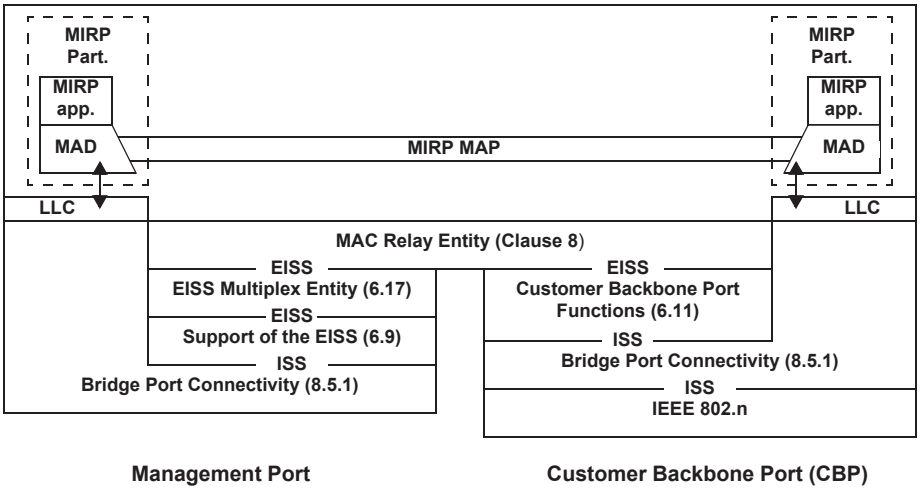

Figure 39-2—Operation of MIRP in a B-component

39.1.1 Behavior of I-components

Since PBBs are insulated from C-MAC addresses by the I-TAG, MVRP Participants in I-components are peers of MVRP Participants in other I-components, and not with MVRP Participants attached to PNPs in B-components or BCBs. In the case that an I-component is configured for some number of VIPs, each serving some number of VLANs, a single MIRPDU transmitted or received over the PIP takes the place of the individual MVRPDUs that would otherwise be transmitted or received over those VIPs.

An I-component supporting MIRP shall:

a) Implement the MIRP application as indicated in 39.2;
b) Implement an MVRP/MIRP attributes translation function as indicated in 39.2.1.1; and
c) Support operation only as an MRP New-Only Participant (10.6).

39.1.2 Behavior of B-components

As illustrated in Figure 39-2, there are any number of MIRP Participants in a B-component, each on a CBP, and each containing an instance of the MIRP application and a MIRP MAD, with the MADs interacting via MAP. In addition, at most one MIRP Participant is attached to a Port that is not a CBP. This port can be a PNP, or a Management Port with no attachment to an external LAN. The latter case is shown in Figure 39-2.

A B-component supporting MIRP shall:

a) Implement the MIRP application as indicated in 39.2; and
b) Support operation as an MRP New-Only Participant (10.6).

39.2 Definition of the MIRP application

39.2.1 Definition of MRP elements

39.2.1.1 S-VID and I-SID mapping in an I-Component

MVRP MAP (11.2.1, 10.3) propagates information among the MVRP MADs and the MIRP MAD. But, since MVRP MADs support 12-bit VID values, and the MIRP MAD supports 24-bit I-SID values, a translation function is required to map the VIP-ISID to or from S-VIDs statically configured on the VIP.

c) When a “new” MIRP declaration is received on a given VIP as a result of receiving an MIRPDU from the attached LAN (MAD_Join.indication), the MAD_Join.request with the *new* parameter set that is generated by the MIRP MAD is translated to a MAD_Join.request for each S-VLAN with a Static VLAN Registration Entry of Registration Fixed (New propagated) on that VIP. When any MIRP declaration with the *new* parameter is received on a given VIP as a result of a request from MAP (MAD_Join.request) for any S-VLAN with a Static VLAN Registration Entry of Registration Fixed (New propagated) on that VIP, it is translated to a MAD_Join.request for that VIP’s I-SID with the *new* parameter set. All other requests are discarded.

NOTE—If many S-VLANs are configured per VIP, then using an MVRP New-Only Participant (11.2.6) offers more detailed control of MAC address flushing than does MIRP, at some cost in bandwidth and processing effort.

39.2.1.2 I-SID translation in a B-component

If a Backbone Service Instance table (6.11) on a CBP implements the Local Service Instance Identifier (Local-SID) field, the attribute values encoded in MIRPDUs by the MIRP Participants in CBPs shall be Local-SID values. The attribute values transferred by MAP in the B-component and encoded in MIRPDUs by the MIRP Participant on a non-CBP Port shall be Backbone-SID values.

39.2.1.3 MAP Context for MIRP

The MIRP MAP Context identifies the set of Ports that form the applicable topology for the propagation of the MIRPDUs among the MIRP Participants. Within a single I-component, the MIRP Participants on PIPs behave as independent end stations from an I-SID registration perspective and correspondingly there is no further propagation of the MIRPDUs. As described in 39.2.1.1, the S-VID/I-SID translation function allows the MIRP MADs to communicate with MVRP MADs. Thus, New messages can propagate throughout a concatenated network of PBNs (via MVRP) and PBBNs (via MIRP).

Within a single B-component, there may be multiple MIRP MAP Contexts. The reason for having separate MIRP MAP Contexts is to collect and distribute MIRP information bound for or received from MIRPDUs that use different combinations of B-VIDs and MAC addresses, as chosen by the network administrator via managed objects (12.16.1). A Port in a B-component supporting a MIRP Participant, either an administratively chosen PNP or Management Port, or a CBP, can participate in more than one MIRP Context. The Ports of a B-component comprising a given MIRP Context is a PNP or Management Port, plus the set of CBPs on the B-component for which the following are true:

a) The CBP is in the Member set (8.8.9) for the B-VID.
b) If the MIPRDU destination_address for the CBP is the Default Backbone Destination address, the FDB does not filter that B-VID and MAC address on the Port.

In a B-component, the parameters controlling MIRPDU addressing (39.2.1.6) control the number of MIRP MAP Contexts as follows:

c) If a single destination_address and B-VID are used for all MIRPDUs [item a) in 39.2.1.6] then there is a single MIRP MAP Context.
d) If the Nearest Customer Bridge group address (Table 8-1) used with a B-VID from a Backbone Service Instance table [item b) in 39.2.1.6], then there is a separate MIRP MAP Context for each B-VID that appears in the CBP Backbone Service Instance table (6.11) of any CBP with a configured MIRP Participant.
e) If the Default Backbone Destination option for the MIRPDU destination_address is used [item c) in 39.2.1.6], then there is a separate MIRP MAP Context for each combination of Default Backbone Destination and B-VID in the CBP Backbone Service Instance table (6.11) of any CBP with a configured MIRP Participant.

The MIRP Participant on a CBP propagates information for a particular I-SID between the CBP MIRP MAD and the appropriate MIRP MAP Context, as determined by the CBP's Backbone Service Instance table and the addressing selection parameters (39.2.1.6). Thus, a CBP MIRP MAD may exchange requests and indications with multiple MIRP MAP Contexts.

NOTE 1—MIRPDUs cannot pass through the CBP functions (6.11) because they have no I-TAG. Readers can see from Figure 39-2 and Figure 39-3 that this isolates the MIRPDUs exchanged among PNPs, Management Ports (and CBPs in Figure 39-3) over the backbone from the MIRPDUs exchanged over the various I-component–to–CBP links.

NOTE 2—See 39.2.2 for an alternate model for MIRP operation in a B-component and the MIRP MAP Context.

39.2.1.4 MAP Context identification for MIRP

In an I-component, there is only one MAP Context.

In a B-component, the vlan_identifier and destination_address of an MIRPDU received on a PNP or Management Port serve to identify the MIRP MAP Context as defined in 39.2.1.3. In a CBP, the MIRP MAP Context used to propagate information is determined by CBP Backbone Service Instance table (6.11) entry for each I-SID value propagated. An MIRPDU that corresponds to no MAP Context configured on the receiving B-component is discarded.

39.2.1.5 MIRP application addressing in an I-component

The source MAC address for an MIRPDU is the MAC address of the PIP.

The destination MAC address for an MIRPDU transmitted from a PIP shall be the Nearest Customer Bridge group address, (01-80-C2-00-00-00, see Table 8-1).

MIRPDUs transmitted and received on a PIP carry no VLAN tag and have no vlan_identifier.

NOTE—An MIRPDU transmitted by a PIP needs no B-TAG because it is connected to a CBP (see Figure 25-4) that either has an MIRP Participant to receive the untagged MIRPDU, or if not, discards the MIRPDU (39.2.1.3).

39.2.1.6 MIRP application addressing in a B-component

The source MAC address for an MIRPDU is the MAC address of the Port from which it is transmitted.

For a MIRP Participant attached to a CBP, the destination MAC address for an MIRPDU transmitted shall be the Nearest Customer Bridge group address, (01-80-C2-00-00-00, see Table 8-1). MIRPDUs shall be transmitted from a CBP without a VLAN tag.

For the MIRP Participant attached to a PNP or Management Port, there are three choices, selectable via managed variables [see item k) in 12.16.1.1.3], for the destination MAC address and B-VLAN on transmitted MIRPDUs:

a) The destination_address is the Nearest Customer Bridge group address (Table 8-1), and the vlan_identifier is the MIRP B-VID [item c) in 12.16.1.2.2].
b) The destination_address is the Nearest Customer Bridge group address (Table 8-1), and the vlan_identifier is a B-VID from the CBPs' Backbone Service Instance tables (6.11).
c) The destination_address is a Default Backbone Destination from the CBPs' Backbone Service Instance tables (6.11), and the vlan_identifier is a B-VID from those tables.

In case b) or case c), it is possible that different CBPs in the serving I-SIDs in the same MIRP MAP Context (39.2.1.3) can be configured differently. For each I-SID value's message in the MIRPDU, the MIRP Participant on the PNP or Management Port uses the Backbone Service Instance table from the CBP with the lowest numerical Port Number to determine the {destination_address, vlan_identifier} pair to use for that I-SID value.

A separate MIRPDU is transmitted for each separate MIRP MAP Context. If multiple {destination_address, vlan_identifier} pairs are generated by different I-SIDs within a single MIRP MAP Context, then the MIRP Participant shall transmit at least one MIRPDU for each distinct pair.

NOTE 1—The network administrator can use the destination_address and vlan_identifier configuration choice to optimize either for the fewest transmitted MIRPDUs by using case a), for the fewest unnecessarily addressed I-components by using case c), or for a balance of these two conflicting optimizations by using b).

NOTE 2—If different B-components in a single PBBN are configured differently for MIRP application addressing, then MIRPDUs can be lost or misinterpreted, because the different B-components can classify MIRPDUs in different MAP Contexts.

NOTE 3—See 39.2.2 for an alternate model for MIRP operation in a B-component and MIRPDU addressing.

39.2.1.7 MIRP application EtherType

The EtherType used for MIRPDUs shall be the MIRP EtherType identified in Table 10-2.

39.2.1.8 MIRP ProtocolVersion

The ProtocolVersion for the version of MIRP defined in this standard takes the hexadecimal value 0x00.

39.2.1.9 MIRP AttributeType definitions

MIRP defines a single Attribute Type (10.8.2.2) that is carried in MRP exchanges, as follows:

Attributes identified by the I-SID Vector Attribute Type are instances of VectorAttributes (10.8.1), used to identify a sequence of values of I-SIDs. The value of AttributeType used to identify the I-SID Vector Attribute Type in MRPDUs (10.8.2.2) shall be 1.

39.2.1.10 MIRP FirstValue definitions

The FirstValue field in instances of the I-SID Vector Attribute Type shall be encoded in MRPDUs (10.4) as three octets, taken to represent an unsigned binary number, and equal to the value of the VIP-ISID parameter for the VIP.

The range of permitted I-SID values that can be encoded in the FirstValue fields in MIRP is restricted to those not listed in Table 9-3.

39.2.1.11 Administrative controls

MIRP supports only the Registration Fixed (New propagated) value of the Registrar Administrative Controls (10.7.2) and this value cannot be manipulated by management. Therefore, the MRP Registrar Administrative Control (12.7.7.1, 12.7.7.2) can only take the value New propagated.

The provision of static control over the ability of Applicant state machines to participate in protocol exchanges is achieved by means of the Applicant Administrative Control parameters associated with the operation of MRP (10.7.3). Where management capability is implemented, the Applicant Administrative Control parameters can be applied and modified by means of the management functionality defined in 12.9.

The management controls in Clause 12 operate per Bridge Port, but a MIRP Participant is attached to a PIP, which is not a Bridge Port. Therefore, if MIRP is enabled on any VIP on a PIP, then the MIRP Participant is enabled on that PIP. If MIRP is disabled on all of the VIPs on a PIP, then the MIRP Participant on the PIP is disabled.

The choice of destination_address and vlan_identifier used in an MIRPDU from a B-component are made by an enumerated configuration parameter [item d) in 12.16.1.2.2] and a B-VLAN configuration parameter [item c) in 12.16.1.2.2].

39.2.2 Alternate MIRP model for B-components

An alternate model for the operation of MIRP in a B-component is illustrated in Figure 39-3. This model is perfectly interoperable with that presented in 39.2.1 and Figure 39-2, is indistinguishable in terms of required protocol behavior from that model, and thus can be used to implement MIRP. In this alternate model, there is a pair of communicating MIRP Participants in each CBP, separate from a similar pair in every other CBP, with no MIRP Participant on any PNP or management Port. The LAN-facing MIRP Participant (the right-hand MIRP Participant in Figure 39-3) corresponds to the CBP MIPR Participant described in 39.2.1. The Relay-facing MIRP Participant (the left-hand MIRP Participant in Figure 39-3) is attached to the EISS Connectivity (39.2.2.1). Its functions correspond to those of the MIRP Participant on a PNP or Management Port in 39.2.1 and Figure 39-2.

NOTE 1—Because the CBP functions (6.11) do not pass frames without I-TAGs, the Relay-facing MIRP Participant can exchange MIRPDUs only through the MAC Relay Entity, and the LAN-facing MIRP Participant only through the LAN.

NOTE 2—The only difference between the models in Figure 39-2 and Figure 39-3 that visible to an observer external to the B-component is that the alternate model can issue MIRPDUs with different source_address parameters, while a the PNP model issues all MIRPDUs with the same source_address. Since MRP and MIRP make no use of that parameter, this difference does not affect the operation of the protocol.

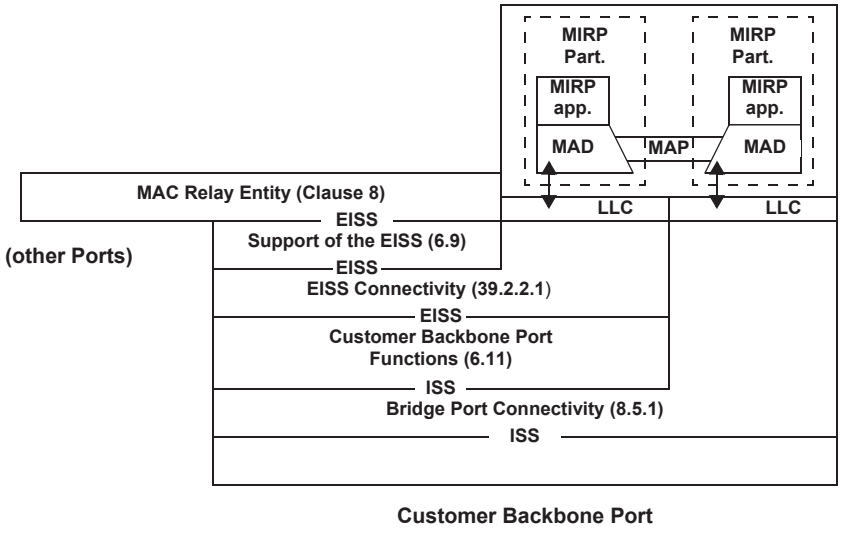

Figure 39-3—Alternate model for MIRP in a B-component

39.2.2.1 EISS Connectivity

The EISS Connectivity function is identical to the Bridge Port Connectivity of 8.5.1, except that it supports the EISS (6.8) instead of the ISS (IEEE Std 802.1AC).

Each EM_UNITDATA.indication provided by the lower EISS access point (Figure 39-3) shall result in a corresponding EM_UNITDATA.indication with identical parameters at each of the access points supporting the MAC Relay and Higher Layer Entities. (Only one such Higher Layer Entity is shown in Figure 39-3.) Each EM_UNITDATA.request from the EISS access point supporting the MAC Relay Entity shall result in a corresponding EM_UNITDATA.indication with identical parameters at each of the access points for the Higher Layer Entities, and a corresponding EM_UNITDATA.request with identical parameters at the lower access point. Each EM_UNITDATA.request from an ISS access point supporting a Higher Layer Entity shall result in a corresponding EM_UNITDATA.indication with identical parameters at the access points for the MAC Relay Entity, and at other access points for Higher Layer Entities, and a corresponding EM_UNITDATA.request with identical parameters at the access point for the LAN.

The MAC_Enabled, MAC_Operational, and operPointToPointMAC status parameters for the EISS access point for the MAC Relay Entity and Higher Layer Entities shall take the same value as that for the lower access point if that is present, and shall be True otherwise (i.e., if the Port is a Management Port).

39.2.2.2 Alternate MIRP MAP Context

There is a single MIRP MAP Context per CBP, that includes both of the MIRP Participants on that CBP but no MIRP Participant on any other CBP.

39.2.2.3 Alternate MIRPDU addressing

The addressing requirements for the two MIRP Participants on a CBP are different. The LAN-facing MIRP Participant behaves as described in 39.2.1.6. The Relay-facing MIRP Participant follows the rules described for the PNP or Management Port in 39.2.1.6. Since there is only one Backbone Service Instance table (6.11) per CBP, there is no ambiguity with regard to MIRPDU addressing. The MIRPDU addressing control parameters described in 39.2.1.6 apply to every Relay-facing MIRP Participant.

NOTE—The model in Figure 39-3 results in the CBPs communicating MIRP information via MIRPDUs, instead of via the MIRP MAP, as in Figure 39-2, and all of those MIRPDUs would be output to the rest of the PBBN, as well.

39.2.3 Use of “new” declaration capability

MIRP supports the Registration Fixed (New propagated) value for the Registrar Administrative Controls for a Port in a Static VLAN Registration Entry. MIRP will accept and propagate a New Message received on that Port for that VLAN and propagate it to all other Ports.

When any MIRP declaration marked as “new” is received on a given VIP, either as a result of receiving an MIRPDU from the attached LAN (MAD_Join.indication), or as a result of receiving a request from the MAP (via the S-VID/I-SID translation function [39.2.1.1]) for the MIRP Application (MAD_Join.request), any entries in the I-component’s FDB for that Port and for the VLANs corresponding to the attribute value in the MAD_Join primitive are removed.

39.2.4 Attribute value support requirements

Implementations of MIRP shall be capable of supporting all attribute values in the range of possible values that can be registered using MIRP. An I-component shall be capable of maintaining current state information for at least 4094 attributes in the range of possible values. A CBP implementation shall support the full range of attribute values that are supported, in turn, by its Backbone Service Instance table.

39.2.5 MRP Message filtering

A MIRP Participant operates in Registration Fixed (New propagated) mode only. Therefore, any MIRP Message for an attribute that is not a VIP-ISID (for an I-component) or a Local-SID or Backbone-SID (for a CBP) is ignored by a MIRP Participant.

40. Edge Virtual Bridging (EVB)

Figure 40-1 provides an overview of the EVB architecture. An end station that supports the attachment of one or more virtual stations is said to be an EVB station. Each virtual station has at least one Virtual Station Interface (VSI). Each virtual station communicates with other virtual stations or other stations on the Bridged Network via the edge relay (ER) to which it is attached (see 3.76).

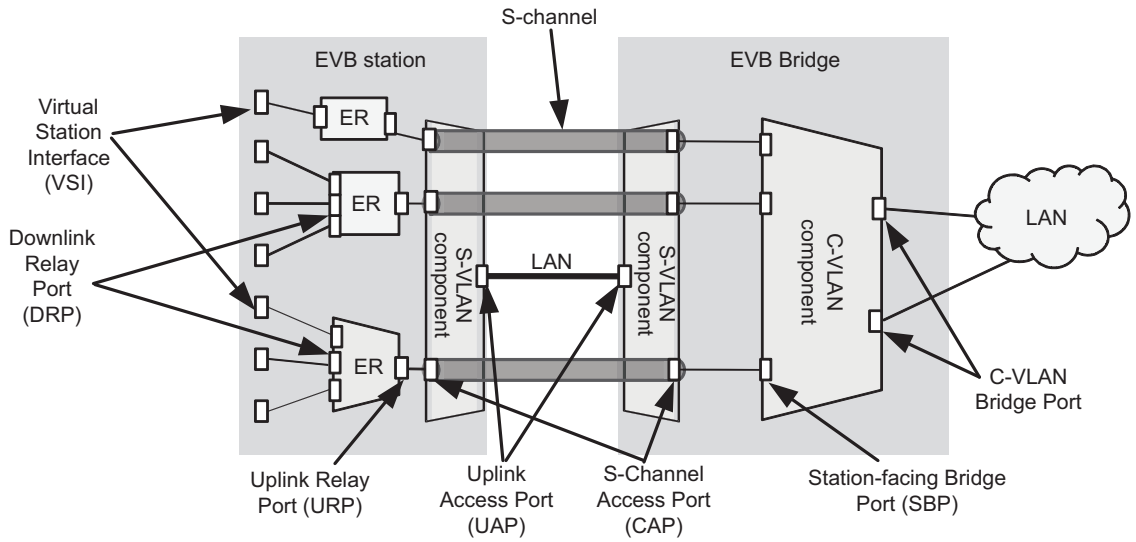

Figure 40-1—EVB architecture overview

An ER supports local relay among virtual stations and/or relay between a virtual station and other stations on the Bridged Network through an EVB Bridge. When forwarding of frames from one DRP to one or more other DRPs associated with the same ER (i.e., local relay) is not supported, then forwarding of traffic from one DRP to one or more other DRPs is performed by the EVB Bridge, utilizing reflective relay (8.6.1).

Connection between a DRP and a virtual station is achieved via a VSI. Traffic from a VSI traverses an internal LAN connecting the DRP to the virtual station. The operation of an ER does not result in any modifications to relayed frames over and above the normal tagging and untagging functions of a VLAN Bridge. ERs do not participate in, or affect, spanning tree operation; it is therefore necessary that the logical connectivity maintained within the station is always loop-free (5.24.1).

Figure 40-1 shows a 2-port ER within the EVB station; this illustrates the fact that even where a single VSI is supported by an S-channel, an ER is present in order to provide C-tagging, reserved address filtering (per Table 8-1) and support for the VSI Discovery and Configuration Protocol (VDP, Clause 41), the Edge Control Protocol (ECP), the EVB TLV (D.2.12), and LLDP (IEEE Std 802.1AB).

Each VSI instance is assigned a VSI manager ID, VSI Type Identifier (VTID), and VSI Instance Identifier (VSIID). VDP associates a VSI instance and its related VID(s), MAC address(es), GroupID(s), VSI manager ID, VTID,[49] and VSIID with an SBP. Similarly, VDP de-associates a VSI instance from an SBP.

VDP can also be used to associate a single VTID with, or de-associate a single VTID from the SBP. In this case, the VSI instance does not contain any MAC addresses, VIDs, or Group IDs, and uses the wildcard VID format (41.2.9.1). Only the most recent associate command is used to configure the VTID for the SBP.

[49] The meaning of the VTID is decided by local system and network management.

An ER supports relaying of frames associated with one or more VSIs. In order to achieve this, an ER can support two types of operation. In the first type, referred to as virtual edge bridge (VEB), traffic transferred from one DRP to another DRP of the same ER is forwarded directly by that ER. In the second type, referred to as VEPA, traffic transferred from one DRP to another DRP of the same ER is forwarded onto a single URP beyond the ER to the EVB Bridge. In this case, the EVB Bridge's SBP is enabled with reflective relay (40.4, 8.6.1); this allows the frame to be reflected back to the same ER from which it was received by the EVB Bridge. The ER can then forward the frame to the destination. Thus, in the second mode, all traffic transits the EVB Bridge's SBP and is subject to, for example, filtering or policing behavior associated with the EVB Bridge.

NOTE—Connection between an EVB Bridge and an ordinary end station takes place via a C-VLAN Bridge Port, not an SBP.

An S-channel is a point-to-point S-VLAN that spans a pair of Port-mapping S-VLAN components (22.6.4) and can be used to interconnect an ER and the C-VLAN component of an EVB Bridge. Multiple S-channels can share the use of a LAN. The use of multiple S-channels allows the EVB station to support multiple ERs. The endpoint of an S-channel is known as an S-channel Access Port (CAP); frames are S-tagged on entry to, and are untagged on exit from, the S-VLAN component through a CAP.

EVB TLVs (D.2.12) exchanged via LLDP allow an EVB station and an EVB Bridge to exchange information related to the use of reflective relay and other operational parameters. Each ER has an LLDP database at its URP. Each ER can also have an LLDP database at each DRP.

Each URP and each SBP has an instance of ECP (Clause 43) used to support the VDP. These instances of ECP use the Nearest Customer Bridge address as the destination for frames exchanged between the URP and SBP. VDP TLVs are packed into PDUs that are handed to ECP for delivery. ECP provides reliable delivery of VDP PDUs.

40.1 EVB architecture without S-channels

Figure 40-2 illustrates the relationship of the EVB entities to the Bridge architecture when no S-channels are supported and no Port-mapping S-VLAN components are implemented. In this configuration, the EVB station and EVB Bridge may exchange an S-channel Discovery and Configuration Protocol (CDCP) TLV over the Nearest non-TMPR Bridge address indicating that the S-VLAN component is not present. If the CDCP TLV managed object does not exist in the LLDP database, then the transmitting station or Bridge is assumed to not support S-channels. A URP or an SBP can send a CDCP TLV. If the EVB station supports the CDCP TLV then the nearest non-TPMR LLDP database is located at the URP. If the EVB Bridge supports the CDCP TLV then the nearest non-TPMR LLDP database is located at the SBP.

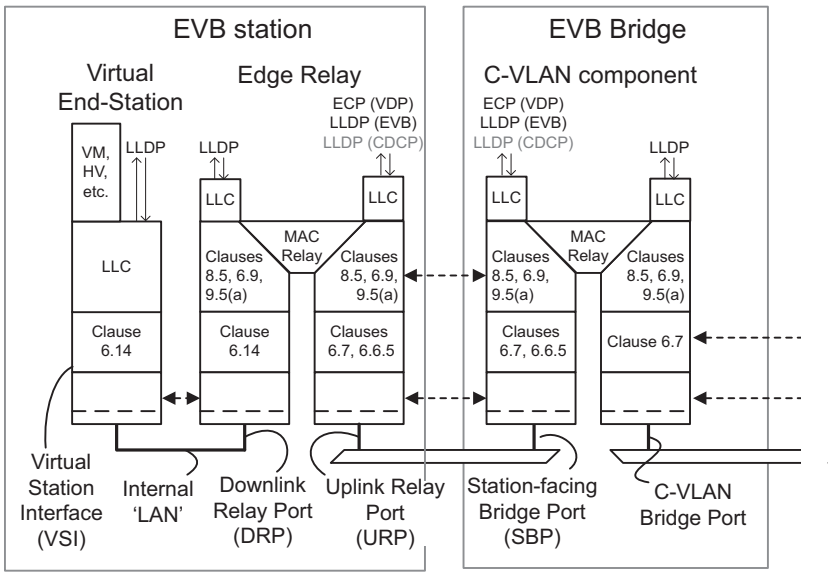

Figure 40-2—EVB architecture without S-channels

40.2 EVB architecture with S-channels

Figure 40-3 shows the relationship of the EVB entities to the Bridge architecture when S-channels are supported. In this configuration, the EVB station and Bridge build nearest non-TPMR LLDP databases at their Uplink Access Ports (UAPs) and use them to exchange CDCP TLVs. Both the EVB station and EVB Bridge set the SComp parameter in the CDCP TLV to TRUE indicating they have an S-VLAN component. The CDCP operating on the CDCP TLVs exchanged by LLDP is used to configure the S-channels.

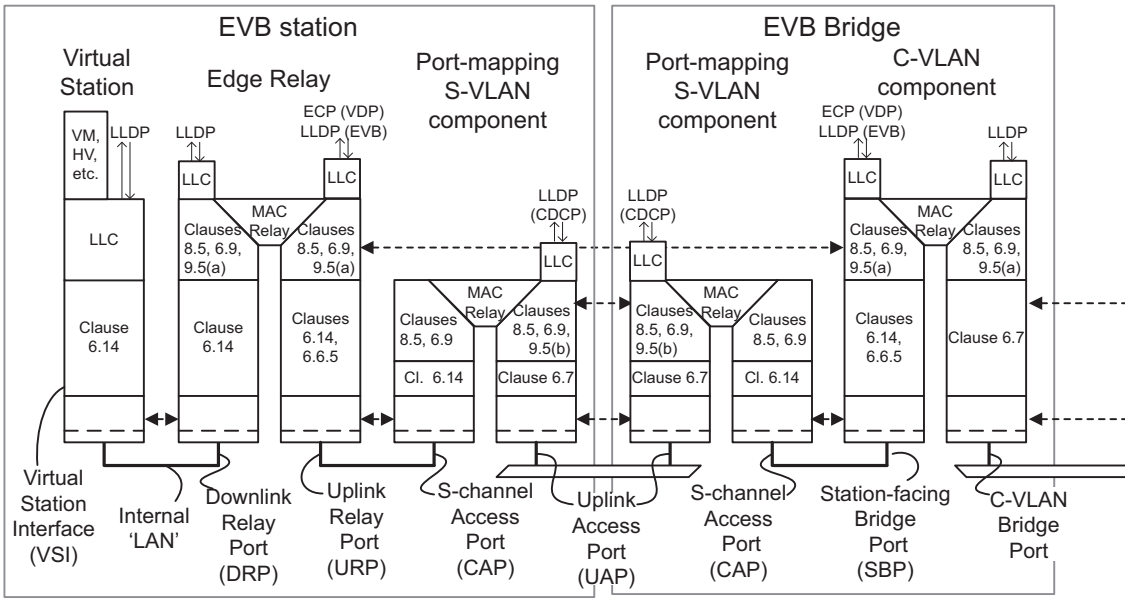

Figure 40-3—EVB architecture with S-channel

EVB stations and EVB Bridges use Port-mapping S-VLAN components (5.6, 22.6.4) to instantiate S-channels. Each S-channel connects a CAP on the EVB station to a CAP on the EVB Bridge. The CAP on an EVB station connects to a single URP on an ER via an internal LAN. The CAP on an EVB Bridge connects to a single SBP on the C-VLAN component via an internal LAN. There is a 1:1 relationship between a CAP and an SBP of the EVB Bridge, and a 1:1 relationship between a CAP and a URP of the EVB station. S-channel support allows the EVB station and EVB Bridge to support multiple ERs on a LAN. Each S-channel is associated with the URP of a distinct ER.

Figure 40-4 shows the relationship between S-channels and CAPs and the positioning of a station's internal and external LANs. When S-channels are supported, each physical LAN can be used to support multiple S-channels identified on the LAN by S-tagging. The S-channels are supported by one Port-mapping S-VLAN component for each UAP. Each Port-mapping S-VLAN component within an EVB station can be identified by its single UAP. A CAP is uniquely identified by the combination of the UAP of the S-VLAN component and the S-VID of the S-channel. Each CAP attaches by internal C-tagged LANs to a single URP or SBP. The C-VLANs carried over each S-channel are determined by configuration of the EVB station and of the C-VLAN component within the EVB Bridge.

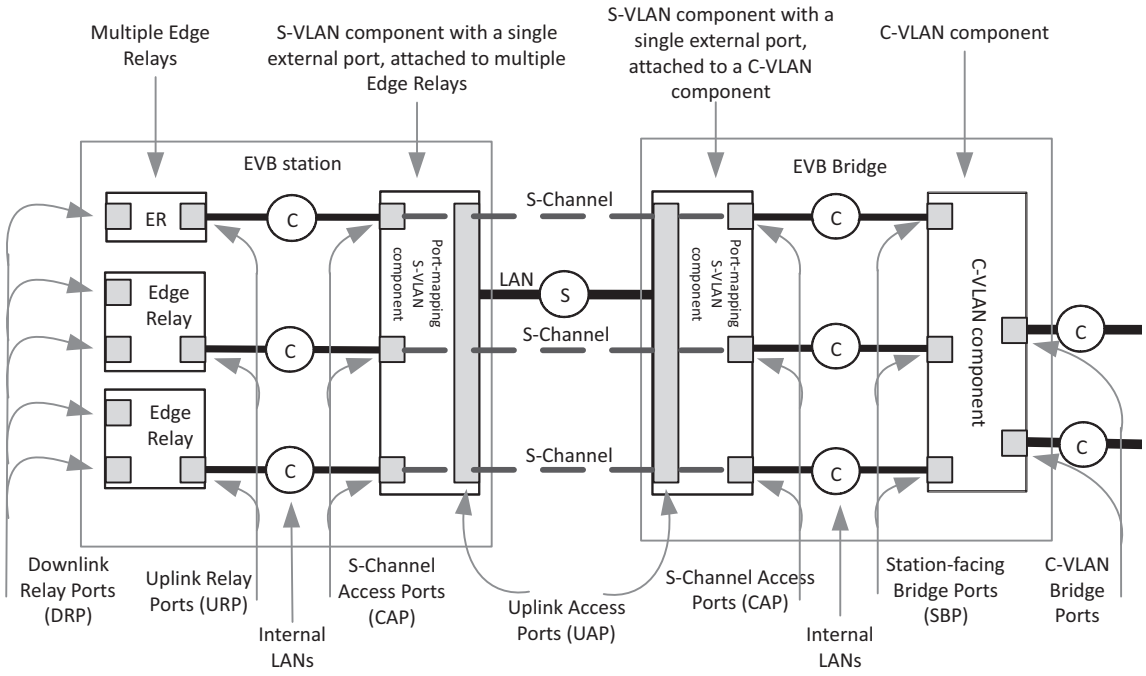

Figure 40-4—EVB components and internal LANs with S-channels

NOTE—As a result of normal Bridge behavior described in 6.9, the priority carried in the C-TAG is regenerated at the CAP to form the S-TAG priority.

The C-VLAN component of the EVB Bridge is a standard C-VLAN component (5.5) that additionally supports reflective relay (40.4, 8.6.1), the EVB LLDP TLV, and VDP.

When a UAP table entry (12.26.4.1) is created, a Port-mapping S-VLAN component is instantiated and the following actions are taken automatically:

a) The UAP is configured to perform as follows:
   1) Admit all frames (6.9).
   2) Have a PVID parameter equal to the default S-channel S-VID (6.9, 40.3).
   3) Be included in the member set for the default S-channel S-VID (8.8.10).
   4) Be a member of the untagged set for the default S-channel S-VID (8.8.2).
   5) Be included in the member set for all S-VIDs of active S-channels.
b) An S-channel Interface table entry is created if one does not already exist for the default S-channel. This table provides the equivalent functionality of the following:
   1) Creating a CAP for the default S-channel.
   2) Configuring the CAP to accept only un-S-tagged frames (6.9).
   3) Setting the member set for the default S-channel's S-VID to include the CAP.
   4) Setting the CAP's PVID to the default S-channel's S-VID.
   5) Adding the CAP to the default S-channel S-VID's untagged set.
   6) Setting filters on the CAP for the Nearest Bridge and Nearest non-TPMR Bridge group MAC addresses.
   7) In the case of an EVB Bridge allocating (or creating) an SBP on the C-VLAN component attached to the CAP by an internal LAN.
c) An instance of LLDP is started on the UAP transmitting a local database on the Nearest Non-TPMR Bridge Address and including the CDCP TLV.
d) CDCP is started on the UAP and configured with the parameters specified when the UAP was created.
   1) If the CDCP role is "B," then CDCP will wait for new S-channel creation requests. As new requests are found, CDCP creates new S-channel interface table entries for each new S-channel and deletes entries when S-channels are removed.
   2) If the CDCP role is "S," then CDCP uses the S-channel interface table to create the list of S-channel Identifiers (SCIDs) for the S-channels it is requesting from the "B" side.

40.3 Asymmetric EVB architecture without S-channels

Figure 40-5 and Figure 40-6 illustrate the relationship of the EVB entities to the Bridge architecture when S-channels are supported by only one side at a time; either the EVB Bridge or EVB station, but not both simultaneously. In these configurations, the EVB entity with S-channel support will advertise it has an S-VLAN component by building a nearest non-TPMR LLDP databases at its UAP and including the CDCP TLV with the parameter SComp set to TRUE. The EVB entity without S-channel support may advertise a Nearest non-TMPR Bridge LLDP database with the CDCP TLV indicating an SComp parameter set to FALSE. CDCP is assumed not to be supported by the peer EVB entity until a CDCP TLV has been received.

Each Port-mapping S-VLAN component within an EVB entity supports an internal default S-channel identified by S-VID 1 and uses it to pass untagged frames to its UAP. This default S-channel is always present in the entity supporting an S-VLAN component. In the asymmetric configurations, frames from the system without S-channel support are carried over the default S-channel within the system that has S-channel support.

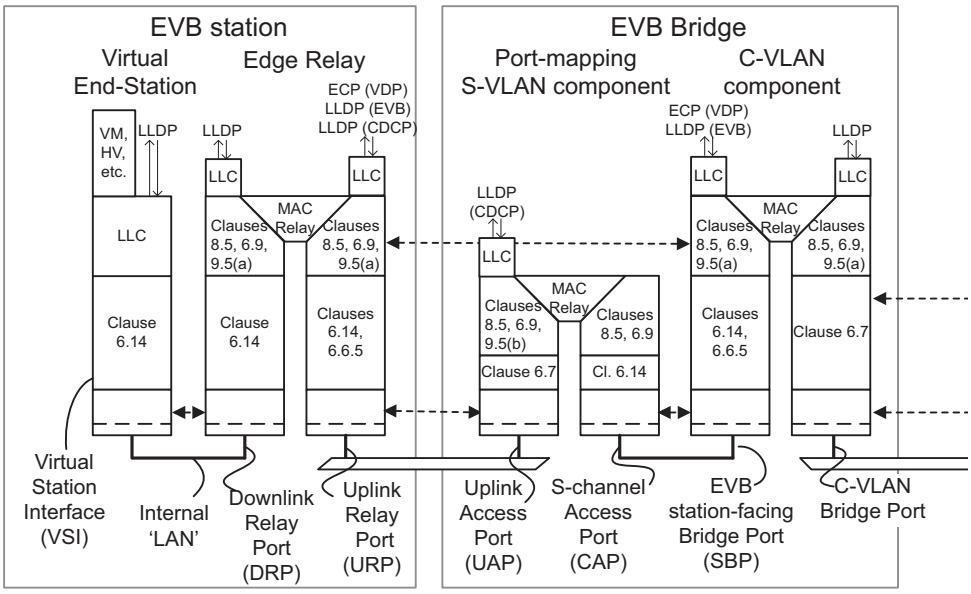

Figure 40-5—EVB architecture without S-channels, with EVB Bridge S-VLAN component

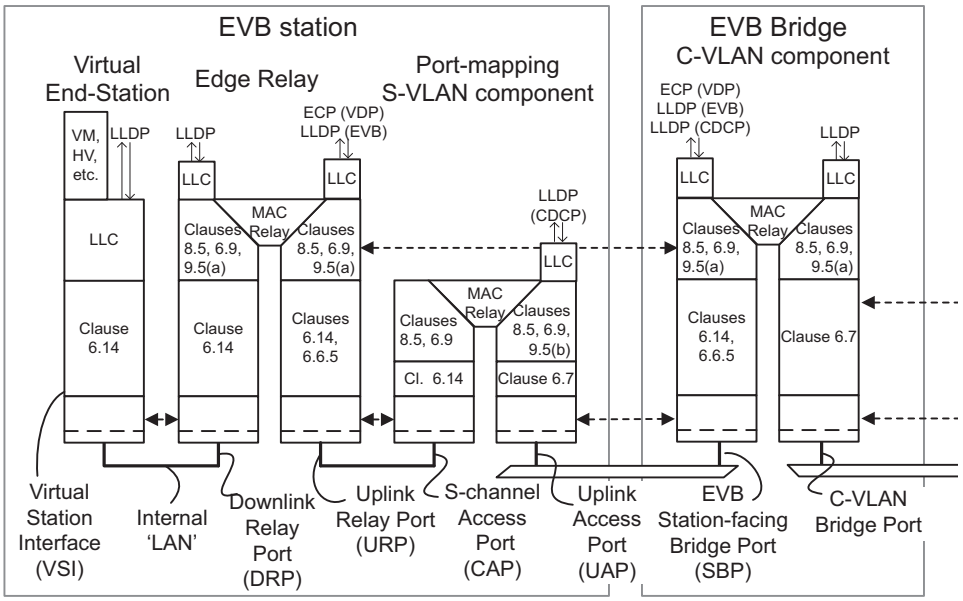

Figure 40-6—EVB architecture without S-channels, with EVB station S-VLAN component

40.4 EVB status parameters

In EVB Bridges and EVB Stations, an **EVBMode** parameter is associated with each port that provides EVB functionality. The parameter represents the EVB status of the port.

The **EVBMode** parameter determines whether EVB functionality is supported, and in what mode. The parameter can take one of the following values:

a) **EVB Bridge.** The port supports the functionality of an EVB Bridge.
b) **EVB station.** The port supports the functionality of an EVB station.
c) **Not Supported.** The port does not support EVB functionality. This value is assumed if the EVB status parameters are not implemented.
d) **NVO3 Mode.** The port supports the revised EVB functionality to be used in an NVO3 Split-NVE scenario.

40.4.1 EVBMode = Not supported

If the value of the **EVBMode** parameter is **Not Supported**, then no further status parameters are available, EVB functionality is not supported, and the operation of the service associated with the port follows the normal forwarding rules for a Bridge.

40.4.2 EVBMode = EVB Bridge

If the value of the **EVBMode** parameter is **EVB Bridge**, then further parameters are available, as follows:

a) **reflectiveRelayCapable.** If this parameter is TRUE, then the active topology enforcement function is capable of performing reflective relay, as specified in 8.6.1; if FALSE, the active topology enforcement function is not capable of performing reflective relay.

   NOTE 1—The value of the reflectiveRelayCapable parameter is an inherent property of the implementation and is not subject to administrative control.

b) **operReflectiveRelayControl**. If this parameter is TRUE, then reflective relay is enabled; if FALSE, reflective relay is disabled.

   NOTE 2—Reflective relay is enabled if a remote EVB station has requested that it be provided (as determined by protocol exchanges between the EVB station and EVB Bridge) and the EVB Bridge is capable of providing it, or disabled if the EVB station has not requested that it be provided or the EVB Bridge is not capable of providing it.

40.4.3 EVBMode = EVB station

If the value of the **EVBMode** parameter is **EVB station**, then further parameters are available, as follows:

a) **adminReflectiveRelayRequest**. This parameter can take one of two values:
   1) **TRUE**. The attached EVB Bridge is requested to enable Reflective relay.
   2) **FALSE**. The attached EVB Bridge is requested to disable Reflective relay.

   NOTE 1—The value of adminReflectiveRelayRequest is used in the EVB TLV exchanges described in D.2.12 to indicate to an attached EVB Bridge that the EVB station needs reflective relay to be provided. A given EVB station is not required to support both possible values of adminReflectiveRelayRequest.

b) **operReflectiveRelayStatus**. This parameter can take one of three values:
   1) **TRUE.** The EVB Bridge has enabled reflective relay.
   2) **FALSE.** The EVB Bridge has disabled reflective relay.
   3) **Unknown.** It is not known whether the EVB Bridge has enabled reflective relay.

   NOTE 2—The value of operReflectiveRelayStatus indicates whether the EVB Bridge has enabled reflective relay, or whether the EVB Bridge status is not currently known, as determined by protocol exchanges between the EVB station and EVB Bridge. The EVB Bridge status can be unknown during initialization or until the protocol exchanges have completed.

40.4.4 EVBMode = NVO3 Mode

If the value of the **EVBMode** parameter is **NVO3 Mode**, then further parameters are available in 40.5.

40.5 EVB Status Parameter for NVO3 Mode Support

In an NVO3 Split-NVE scenario, tNVE is located in a station that may not be an EVB Station and nNVE is located in a bridge or router that may not be an EVB Bridge. Hence tNVE and nNVE will be used to refer to EVB Station and EVB Bridge revised to support NVO3.

The parameters of the EVB TLV provide the required parameter list. EVB TLV (Annex D) and status parameters are amended to support NVO3.

When **EVBMode** is set to **NVO3 Mode**, an **NVERole** parameter is to be further inspected. The parameter represents the NVE role of the port.

40.5.1 NVERole = nNVE

If the value of the **NVERole** parameter is **nNVE**, then further parameters are available, as follows:

a) **reflectiveRelayCapable.** This parameter is FALSE in NVO3 as tNVE has no requirement to support reflective relay.

NOTE 1—The value of the reflectiveRelayCapable parameter is an inherent property of the implementation and is not subject to administrative control.

b) **operReflectiveRelayControl**. If this parameter is TRUE, then reflective relay is enabled; if FALSE, reflective relay is disabled. In an NVO3 scenario, it is always FALSE since tNVE will not request reflective relay to be enabled.

NOTE 2—Reflective relay is enabled if a remote EVB station has requested that it be provided (as determined by protocol exchanges between the EVB station and EVB Bridge) and the EVB Bridge is capable of providing it, or disabled if the EVB station has not requested that it be provided or the EVB Bridge is not capable of providing it.

c) **BGID**. This parameter is set to TRUE, which indicates that the nNVE wishes to control VID assignments and use the GroupID in VDP exchanges.

NOTE 3—GroupID in VDP is equivalent to VNI ID in NVO3, which is a mandatory parameter to be supported. Both bridge and station sides support it.

40.5.2 NVERole = tNVE

If the value of the **EVBMode** parameter is **tNVE**, then further parameters are available, as follows:

a) **adminReflectiveRelayRequest**. This parameter is set to FALSE, which indicates the attached nNVE is requested to disable reflective relay.

b) **operReflectiveRelayStatus**. This parameter can be FALSE or Unknown.

NOTE 1—The value of operReflectiveRelayStatus indicates whether the nNVE has enabled reflective relay, or whether the nNVE status is not currently known, as determined by protocol exchanges between the tNVE and nNVE. The nNVE status can be unknown during initialization or until the protocol exchanges have completed. However The nNVE status cannot be reflective relay enabled.

c) **SGID**. This parameter is set to TRUE, which indicates that the tNVE can support the use of the GroupID.

NOTE 2—GroupID in VDP is equivalent to VNI ID in NVO3, which is a mandatory parameter to be supported. Both bridge and station sides should support it.

41. VSI Discovery and Configuration Protocol (VDP)

VDP associates (registers) a VSI instance with an Station-facing Bridge Port (SBP) of an EVB Bridge. VDP simplifies and automates virtual station configuration by enabling the movement of a VSI instance (and its related VSI Type information) from one virtual station to another or from one EVB Bridge to another. VDP supports VSI discovery and configuration across a channel interconnecting an EVB station and an EVB Bridge. VDP TLVs are exchanged between the station and the Bridge in support of this protocol.

This clause defines the VDP TLV structure and state machines.

When VDP is used between EVB Station and EVB Bridge, VDP uses ECP (Clause 43) as a transport protocol for VDP TLV exchanges. When ECP is used as a transport protocol for VDP, ECP uses the Nearest Customer Bridge group MAC address (Table 8-1) as the destination address for ECPDUs. Three VDP TLVs are defined as follows:

a) The VSI manager ID TLV (41.1). There is a single instance of this TLV in any ECPDU that carries VDP, and it appears as the first TLV in the ECPDU.
b) The VDP association TLV (41.2). One or more of these TLVs can appear in any ECPDU, following the VSI manager ID TLV.
c) The organizationally defined TLV (41.3).

NOTE 1—If there are multiple VSI managers, then their TLVs are transmitted in separate ECPDUs.

NOTE 2—Beyond the requirement stated, that the VSI manager ID TLV appears as the first TLV in ECPDUs carrying VDP, there are no further constraints placed upon how an implementation chooses to pack VDP TLVs into an ECPDU.

NOTE 3—VDP TLVs are not LLDP TLVs, and the TLV type values used in VDP TLVs are assigned from a distinct number space from those used in LLDP TLVs.

When VDP is used between tNVE and nNVE in an NVO3 Split-NVE scenario, VDP may use ECP (Clause 43) as a transport protocol for VDP TLV exchanges. When ECP is used as a transport protocol for VDP in NVO3, ECP uses a specific unicast MAC address or the Nearest Customer Bridge group MAC address (Table 8-1) as the destination address for ECPDUs. The VDP TLVs used between a tNVE and nNVE are as follows:

d) The VDP association TLV (41.2). One or more of these TLVs can appear in any ECPDU or other transport protocol.
e) The organizationally defined TLV (41.3).

41.1 VSI manager ID TLV definition

Figure 41-1 illustrates the format of the VSI manager ID TLV.

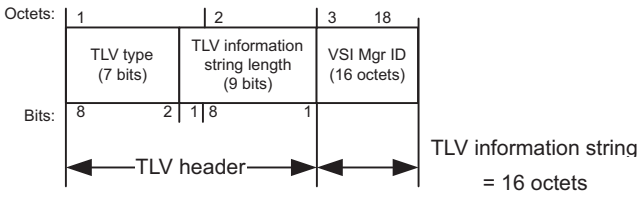

Figure 41-1—VSI manager ID TLV

The VSI manager ID TLV field definitions are contained in 41.1.1 through 41.1.3.

41.1.1 TLV type

The TLV type field takes the value shown in Table 41-1 for VSI manager ID.

Table 41-1—VDP TLV types

TLV type	Value
Pre-Associate	0x01
Pre-Associate with resource reservation	0x02
Associate	0x03
De-associate	0x04
VSI manager ID	0x05
Organizationally defined TLV	0x7F
Reserved for future standardization	0x00, 0x06–0x7E

41.1.2 TLV information string length

This field contains the length of the TLV information string, which is 16 octets.

41.1.3 VSI Manager ID

Identifies the database that should be accessed to get the VSI Type. The value 0 means that the station does not know what VSI Manager ID to use, indicating that the Bridge should select a default value. Any other value is interpreted as an IPv6 address, as defined in IETF RFC 4291.

41.2 VDP association TLV definitions

Figure 41-2 illustrates the format of the VDP association TLV.

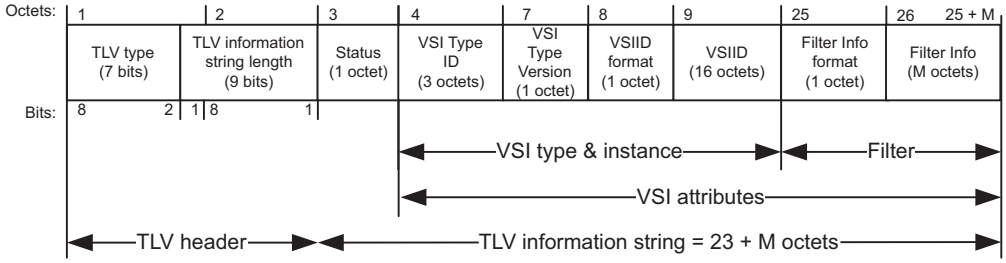

Figure 41-2—VDP association TLV

The VDP association TLV field definitions are contained in 41.2.1 through 41.2.9. The semantics of the VDP association TLV types are defined in 41.2.10.

When the VDP association TLV is sent as a response, the Status field indicates the outcome of the requested operation, and the remaining fields are populated using the information provided in the request or information provided by the EVB Bridge.

41.2.1 TLV type

The TLV type field identifies the type of the VDP association TLV, and can take any of the values shown in Table 41-1 for pre-associate, pre-associate with resource reservation, associate, or de-associate.

41.2.2 TLV information string length

This field contains the length of the TLV information string, calculated as 23 + M octets, where M is the number of octets in the filter info field (41.2.9).

41.2.3 Status

The Status field contains a 4-bit error type, encoded in bits 1–4, and four individual Boolean flags, encoded in bits 5–8.

For all requests, the error type field is reserved for future standardization; it is transmitted as 0x0 and is ignored on receipt.

For all requests, the Boolean flags are interpreted as shown in Table 41-2.

Table 41-2—Flag values in VDP requests

Name	Bit position	Interpretation
M-bit	Bit 5	Indicates that the user of the VSI (e.g., the virtual station) is migrating (M-bit = 1) or provides no guidance on the migration of the user of the VSI (M-bit = 0). The M-bit is used as an indicator relative to the VSI to which the user is migrating.
S-bit	Bit 6	Indicates that the VSI user (e.g., the virtual station) is suspended (S-bit = 1) or provides no guidance about whether the user of the VSI is suspended (S-bit = 0). A keep-alive Associate request with S-bit = 1 can be sent when the VSI user is suspended. The S-bit is used as an indicator relative to the VSI that the user is migrating from.
Req/Ack	Bit 7	Set to 0 to indicate that the TLV contains a request.
N-bit	Bit 8	Indicates that the user of the VSI is NOT migrating (N-bit = 1) or provides no guidance on the migration of the user of the VSI (N-bit = 0).

NOTE—The M-bit is restored to 0 when migration has stopped, either because the migration has succeeded, or it has failed. The S-bit is restored to 0 when the VSI user is no longer suspended.

NOTE 2—Interpretation of M and N bits is described in the following table:

M bit	N bit	Interpretation
0	0	No guidance on the migration of the user of the VSI
0	1	User of the VSI (e.g., the virtual station) is NOT migrating
1	0	User of the VSI (e.g., the virtual station) is migrating
1	1	Reserved

For all responses, the value of the error type indicates the outcome of the request, as shown in Table 41-3, and the Boolean flags are interpreted as shown in Table 41-4.

Table 41-3—Error types in VDP responses

Name	Value	Interpretation
Success	0x0	The VDP Request was successfully completed by the Bridge.
Invalid Format	0x1	The VDP TLV format is invalid.
Insufficient Resources	0x2	The Bridge does not have enough resources to complete the VDP operation successfully.
Unable to contact VSI manager	0x3	The Bridge was unable to contact the VSI manager.
Other failure	0x4	The operation failed for some other reason.
Invalid VID, GroupID, or MAC address	0x5	The operation failed because the VID, GroupID, or MAC address was invalid.
Reserved	0x6–0xF	Reserved for future standardization.
NOTE—"Success" is only interpreted as success by the state machines if all of the flag bits (Table 41-4) are zero.		

Table 41-4—Flag values in VDP responses

Name	Bit position	Interpretation
Hard error	Bit 5	Set to 1 to indicate that the operation failed, and if the same operation is re-tried, it is likely to fail in the same way.
Keep	Bit 6	Set to 1 to indicate that the command was rejected and the state prior to the requested command has been kept.
Req/Ack	Bit 7	Set to 1 to indicate that the TLV contains a response.
Reserved	Bit 8	Reserved for future standardization.

41.2.4 VSI Type ID (VTID)

The VTID is an integer value used to identify a VSI Type.

NOTE—One VTID could describe the VSI Type configuration of multiple VSIs. A VTID is only unique per VSI manager ID.

41.2.5 VSI Type Version

The VSI Type Version is an integer identifier that allows a VSI Manager Database to contain multiple versions of a given VSI Type.

41.2.6 VSIID format

The VSIID format field defines the format of the VSIID field that follows it (41.2.7). The possible values of VSIID format are as shown in Table 41-5.

Table 41-5—VSIID format values

Name	Description	Value
IPv4	An IPv4 address, encoded as specified in IETF RFC 4291.	0x01
IPv6	An IPv6 address, encoded as specified in IETF RFC 4291.	0x02
MAC	An IEEE 802 MAC address (6 octets), with 10 leading octets containing all zeros.	0x03
Local	The interpretation of the VSIID is locally defined.	0x04
UUID	A Universally Unique Identifier (UUID) as specified in IETF RFC 4122.	0x05
Reserved	Reserved for future standardization.	0x00, 0x06 through 0xFF

41.2.7 VSIID

The VSIID is an identifier for the VSI instance. A VSIID is generated when a VSI instance is created. The VSIID remains constant during virtual station migration. The format of the VSIID is determined by the VSIID format field (41.2.6). In cases where the format uses an identifier value that has fewer than 16 octets, the VSIID field is packed out to 16 octets with leading octets containing zeros.

41.2.8 Filter Info format

The Filter Info format field determines the format of the Filter Info field (41.2.9). The Filter Info formats defined by this standard are shown in Table 41-6.

Table 41-6—Filter Info format values

Format	Value
VID (41.2.9.1)	0x01
MAC/VID (41.2.9.2)	0x02
GroupID/VID (41.2.9.3)	0x03
GroupID/MAC/VID (41.2.9.4)	0x04
GroupID/VID/IPv4 (41.2.9.5)	0x05
GroupID/MAC/VID/IPv4 (41.2.9.6)	0x06
GroupID/VID/IPv6 (41.2.9.7)	0x07
GroupID/MAC/VID/IPv6 (41.2.9.8)	0x08
Reserved for future standardization	0x00, 0x09 through 0xFF

41.2.9 Filter Info field

The Filter Info field contains information from which a filter can be constructed. The filter is a set of VID values or a set of MAC/VID values. The MAC address in a MAC/VID value is an individual MAC address. The filter is applied to traffic transiting ports that do not have direct knowledge of the associated VSI, such as an EVB SBP, in order to identify the traffic associated with a particular VSI. This allows such ports to apply a VSI Type to the traffic of an individual VSI. Other devices that have direct knowledge of the traffic associated with a VSI, for example devices that form a 1:1 relationship between a port and VSI, simply provide this information via management interfaces.

The Filter Info field can also contain information that is not part of the filter. In particular, the Filter Info field can contain GroupID values. Like the VID, the GroupID identifies a VLAN. When the number of VLANs in the network is less than 4095, each VLAN can be assigned a VID value that is global within the network. When the number of VLANs in the network exceeds 4094, a globally-scoped VID can no longer be used to uniquely identify each VLAN. Instead, overlapping VIDs may be used in different regions of the network, and a per-region mapping between the global VLAN and the region-specific VID is maintained. In this case, the VLAN is uniquely and globally identified by a GroupID.

When VLANs are identified by GroupID, the station has knowledge of the GroupID but it does not, in general, know the corresponding VID to be used by traffic associated with the VLAN. The Bridge is aware of, or can obtain knowledge of, the VID associated with the specified GroupID. Thus, the station can send GroupID values to the Bridge via the Filter Info field of the VDP Request. The Bridge can map GroupID values to local VID values. The VID is included in the filter constructed by the Bridge and is returned with its corresponding GroupID to the station via the VDP Response.

In the NVO3 Split-NVE scenario, the VNI ID is carried in the lower 3 octets of the GroupID. The upper octet of the GroupID should be all zeros.

NOTE 1—The mechanism by which the EVB Bridge determines the GroupID to local VID associations is outside the scope of this standard.

Additionally, the Filter Info field of a VDP TLV in a VDP Response can specify a Priority Code Point (PCP) value associated with any, or all, of the VID values carried by that VDP Response. The PCP value, if specified, is used by the EVB station as the default PCP value associated with the VSI and VID. The Filter Info field contains a PCP Significant (PS) bit associated with each PCP field, indicating whether the PCP field carries a PCP value (binary 1) or does not carry a PCP value (binary 0). If the PCP field carries a PCP value, then the EVB station can adopt that value as the default PCP value associated with the VSI and VID. When sending data frames associated with a given VSI and VID, the EVB station can determine the PCP value associated with each frame by using an algorithm local to the EVB station. For example, the PCP value can be based on the identity of an application associated with the frame as determined by examining higher layer information. For any given frame, it is possible that the algorithm does not provide a specific value of PCP. In such cases, the PCP field is assigned the value of the default PCP associated with the VSI and VID.

NOTE 2—Specification of a PCP value in the VDP Response does not imply that all frames sent by the EVB station, associated with the VSI and VID, carry the specified PCP. It implies only that, if the EVB station has no other information regarding the PCP value that should appear in that particular frame, then the specified default PCP value is used.

41.2.9.1 VID Filter Info format

The VID Filter Info format specifies that the Format Info field contains a set of VID values to be associated with the VSI instance (41.2.7). Figure 41-3 illustrates the VID Filter Info format.

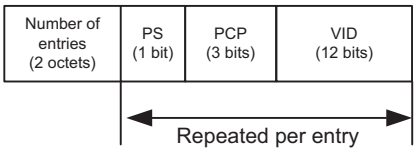

Figure 41-3—VID Filter Info format

The number of VID values in the sequence is specified by the Number of entries field.

The VID field can specify the null VID (see Table 9-2). When the null VID is specified, it is the only VID specified in the Filter Info field (i.e., the Number of entries field is assigned the value 0x0001). Use of the null VID indicates that the set of VID values associated with the VSI is supplied by the Bridge. The Bridge can obtain VID values from the VSI Type whose identity is specified by the VSI Type information in the VDP Request. The set of VID values is returned to the station via the VDP Response.

NOTE—In the case that more than one VID is assigned, the policy that determines how the VIDs are used is outside the scope of this standard.

The Filter Info field can specify the wildcard VID (see Table 9-2). When the wildcard VID is specified, it is the only VID specified in the Filter Info field (i.e., the Number of entries field is assigned the value 0x0001). Use of the wildcard VID value indicates that the VSI Type specified by the VDP Request is designated as the channel VSI Type applied to the EVB SBP associated with the S-channel.

41.2.9.2 MAC/VID Filter Info format

The MAC/VID Filter Info format indicates that the Format Info field specifies a sequence of MAC/VID value pairs to be associated with the VSI instance (41.2.7). Figure 41-4 illustrates the MAC/VID Filter Info format of the Filter Info field.

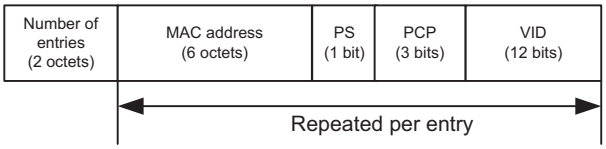

Figure 41-4—MAC/VID filter format

The number of MAC/VID pair values is specified by the field Number of Filter Info entries. Each MAC/VID pair value carries a 6-octet individual MAC address and a 2-octet VID value.

The Filter Info field can specify the null VID for any entry. Use of the null VID indicates that the VID value is supplied by the Bridge.

41.2.9.3 GroupID/VID Filter Info format

The GroupID/VID Filter Info format indicates that the Format Info field specifies a sequence of GroupID/VID pairs to be associated with the VSI instance (41.2.7).

Figure 41-5 illustrates the GroupID/VID Filter Info format of the Filter Info field.

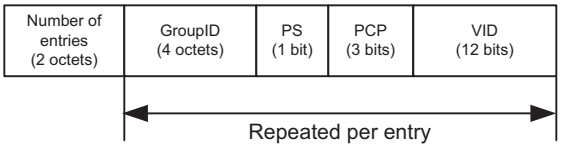

Figure 41-5—GroupID/VID filter format

The number of GroupID/VID pairs is specified by the Number of entries field.

The null VID (see Table 9-2) can be used in a GroupID/VID pair when the GroupID/VID filter format is specified in the VDP Request. In this case, the Bridge is expected to supply the corresponding local VID value in the VDP Response. For this purpose, the Bridge maintains, or has access to, the mapping between GroupID and local VID.

41.2.9.4 GroupID/MAC/VID Filter Info format

The GroupID/MAC/VID Filter Info format indicates that the Filter Info field specifies a sequence of GroupID/MAC/VID triples to be associated with the VSI instance (41.2.7). Figure 41-6 illustrates the GroupID/MAC/VID Filter Info format of the Filter Info field.

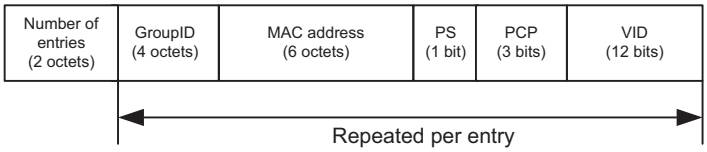

Figure 41-6—GroupID/MAC/VID filter format

The number of GroupID/MAC/VID triples is specified by the value of the Number of entries field. The null VID (see Table 9-2) can be used in a GroupID/MAC/VID triple when the GroupID/MAC/VID filter format is specified in the VDP Request. In this case, the Bridge is expected to supply the corresponding local VID value in the VDP Response. For this purpose, the Bridge maintains, or has access to, the mapping between GroupID and local VID.

41.2.9.5 GroupID/VID/IPv4 Filter Info format

The GroupID/VID/IPv4 Filter Info format indicates that the Format Info field specifies a sequence of GroupID/VID/IPv4 triples to be associated with the VSI instance (41.2.7).

Figure 41-7 illustrates the GroupID/VID/IPv4 Filter Info format of the Filter Info field.

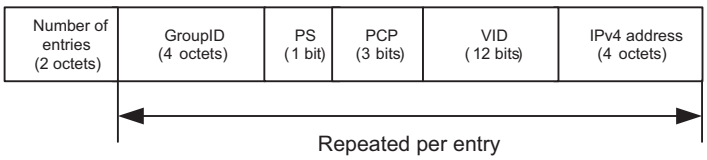

Figure 41-7—GroupID/VID/IPv4 filter format

The number of GroupID/VID/IPv4 triples is specified by the Number of entries field.

The null VID (see Table 9-2) can be used in a GroupID/VID/IPv4 triple when the GroupID/VID/IPv4 filter format is specified in the VDP Request. In this case, the Bridge is expected to supply the corresponding local VID value in the VDP Response. For this purpose, the Bridge maintains, or has access to, the mapping between GroupID and local VID.

41.2.9.6 GroupID/MAC/VID/IPv4 Filter Info format

The GroupID/MAC/VID/IPv4 Filter Info format indicates that the Format Info field specifies a sequence of GroupID/MAC/VID/IPv4 values to be associated with the VSI instance (41.2.7).

Figure 41-8 illustrates the GroupID/MAC/VID/IPv4 Filter Info format of the Filter Info field.

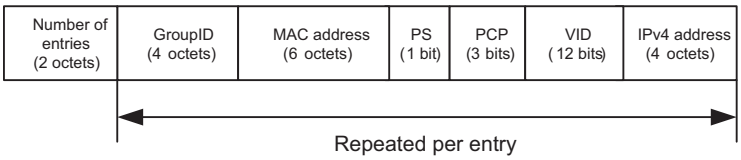

Figure 41-8—GroupID/MAC/VID/IPv4 filter format

The number of GroupID/MAC/VID/IPv4 values is specified by the Number of entries field. The null VID (see Table 9-2) can be used in a GroupID/MAC/VID/IPv4 value when the GroupID/MAC/VID/IPv4 filter format is specified in the VDP Request. In this case, the Bridge is expected to supply the corresponding local VID value in the VDP Response. For this purpose, the Bridge maintains, or has access to, the mapping between GroupID and local VID.

41.2.9.7 GroupID/VID/IPv6 Filter Info format

The GroupID/VID/IPv6 Filter Info format indicates that the Format Info field specifies a sequence of GroupID/VID/IPv6 triples to be associated with the VSI instance (41.2.7).

Figure 41-9 illustrates the GroupID/VID/IPv6 Filter Info format of the Filter Info field.

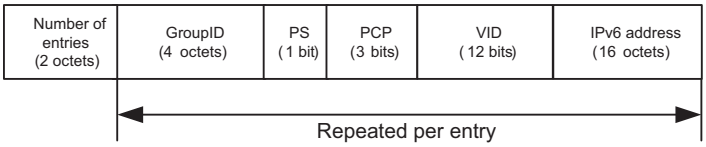

Figure 41-9—GroupID/VID/IPv6 filter format

The number of GroupID/VID/IPv6 triples is specified by the Number of entries field.

The null VID (see Table 9-2) can be used in a GroupID/VID/IPv6 triple when the GroupID/VID/IPv6 filter format is specified in the VDP Request. In this case, the Bridge is expected to supply the corresponding local VID value in the VDP Response. For this purpose, the Bridge maintains, or has access to, the mapping between GroupID and local VID.

41.2.9.8 GroupID/MAC/VID/IPv6 Filter Info format

The GroupID/MAC/VID/IPv6 Filter Info format indicates that the Format Info field specifies a sequence of GroupID/MAC/VID/IPv6 values to be associated with the VSI instance (41.2.7).

Figure 41-10 illustrates the GroupID/MAC/VID/IPv6 Filter Info format of the Filter Info field.

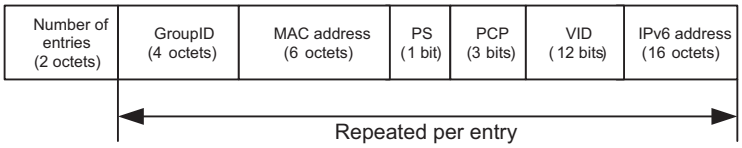

Figure 41-10—GroupID/MAC/VID/IPv6 filter format

The number of GroupID/MAC/VID/IPv6 values is specified by the Number of entries field. The null VID (see Table 9-2) can be used in a GroupID/MAC/VID/IPv6 value when the GroupID/MAC/VID/IPv6 filter format is specified in the VDP Request. In this case, the Bridge is expected to supply the corresponding local VID value in the VDP Response. For this purpose, the Bridge maintains, or has access to, the mapping between GroupID and local VID.

41.2.10 VDP TLV type and status semantics

The following subclauses define the semantics associated with each VDP TLV type.

41.2.10.1 Pre-Associate

The Pre-Associate TLV type is used to pre-associate a VSI instance with a Bridge Port. The Bridge validates the request (see below) and returns a failure Status in case of errors. Successful pre-association does not imply that the VSI Type will be applied to any traffic flowing through the VSI. The pre-associate enables faster response to an associate by allowing the Bridge to obtain the VSI Type prior to an association.

The station can send a Pre-Associate TLV to roll back the station and bridge from associated to pre-associate status.

NOTE—If the VSI Type changes without a corresponding change to its version, then inconsistent behavior can result.

41.2.10.2 Pre-Associate with Resource Reservation

Pre-Associate with Resource Reservation involves the same steps as Pre-Associate (41.2.10.1), but on successful pre-association also reserves resources in the Bridge to prepare for a subsequent Associate request.

The station can send Pre-Associate with a Resource Reservation TLV to roll back the station and bridge from associated to pre-associate with Resource Reservation status.

41.2.10.3 Associate

The Associate TLV Type creates and activates an association between a VSI instance and a Bridge Port. The Bridge allocates any required Bridge resources for the referenced VSI. The Bridge activates the configuration for the VTID. This association is then applied to the traffic flow to/from the VSI instance.

NOTE—The mechanism used by a Bridge to determine the required resources associated with a VTID is outside the scope of this standard.

For a given VSIID, a station may issue an Associate without having previously issued a Pre-Associate or Pre-Associate with Resource Reservation. During normal operations a VSI instance is associated on only one port. During network transitions (e.g., virtual station migration) a VSI instance might be associated with more than one port.

If a Pre-Associate or a Pre-Associate with Resource Reservation had previously been received for a given VSI instance, the Bridge establishes the association and allocates resources based only on the information contained in the Associate TLV. Any resources that had been reserved in order to satisfy a previous Pre-Associate with Resource Reservation, and that are not required in order to establish the association as specified in the Associate, are released.

41.2.10.4 De-Associate

The de-associate TLV Type is used to remove an association between a VSI instance and a Bridge Port. Pre-Associated and Associated VSIs can be de-associated. De-associate releases any resources that were reserved as a result of prior Associate or Pre-Associate operations for that VSI instance.

A de-associate can be initiated either by the station or the Bridge. In the latter case, the Bridge sends a de-associate TLV as if it was a response to a request from the station.

NOTE 1—A Bridge could, for example, issue a de-associate as a consequence of changes in the Bridge's status or configuration.

NOTE 2—The result of the above semantics is that a de-associate can be initiated at any time and by either party.

41.3 Organizationally defined TLV definitions

Figure 41-11 illustrates the format of the organizationally defined TLV.

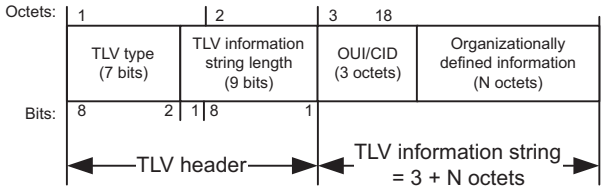

Figure 41-11—Organizationally defined TLV

The organizationally defined TLV field definitions are contained in 41.3.3 and 41.3.4.

41.3.1 TLV type

The TLV type field takes the value shown in Table 41-1 for the organizationally defined TLV.

41.3.2 TLV information string length

This field contains the length of the TLV information string, which is 3 + N octets, where N is the number of octets in the organizationally defined information field (41.3.4).

41.3.3 Organizationally unique identifier (OUI) or Company ID (CID)

Identifies the organization that is responsible for defining the content of the organizationally defined information field (41.3.4). The value of the OUI/CID field is an OUI (see IEEE Std 802) or a CID assigned to that organization by the IEEE registration authority.

41.3.4 Organizationally defined information

The content and interpretation of this field is specified by the organization that owns the OUI or CID value contained in the OUI/CID field (41.3.3).

41.4 Validation rules for VDP TLVs

The following rules apply to the validation of received ECPDUs that carry VDP TLVs:

a) If the first TLV in the ECPDU is not a VSI manager ID TLV (41.1), then the entire ECPDU is discarded without further processing.
b) If the ECPDU contains a TLV of a type that is not recognized by the implementation, then that TLV is discarded and is ignored by the VDP state machines.
c) If a TLV extends past the physical end of the ECPDU, then that TLV is discarded.

41.5 VDP state machines

The station VDP state machine is defined in 41.5.3. A station that supports VDP shall support one instance of the station VDP state machine for each active VSI.

The Bridge VDP state machine is defined in 41.5.2. A Bridge that supports VDP shall support one instance of the Bridge VDP state machine for each active VSI.

41.5.1 State machine conventions

The notational conventions used in the specification of VDP are as stated in Annex E.

41.5.2 Bridge VDP state machine

The Bridge VDP state machine shall implement the function defined in Figure 41-12 and the attendant definitions in 41.5.4 through 41.5.7.

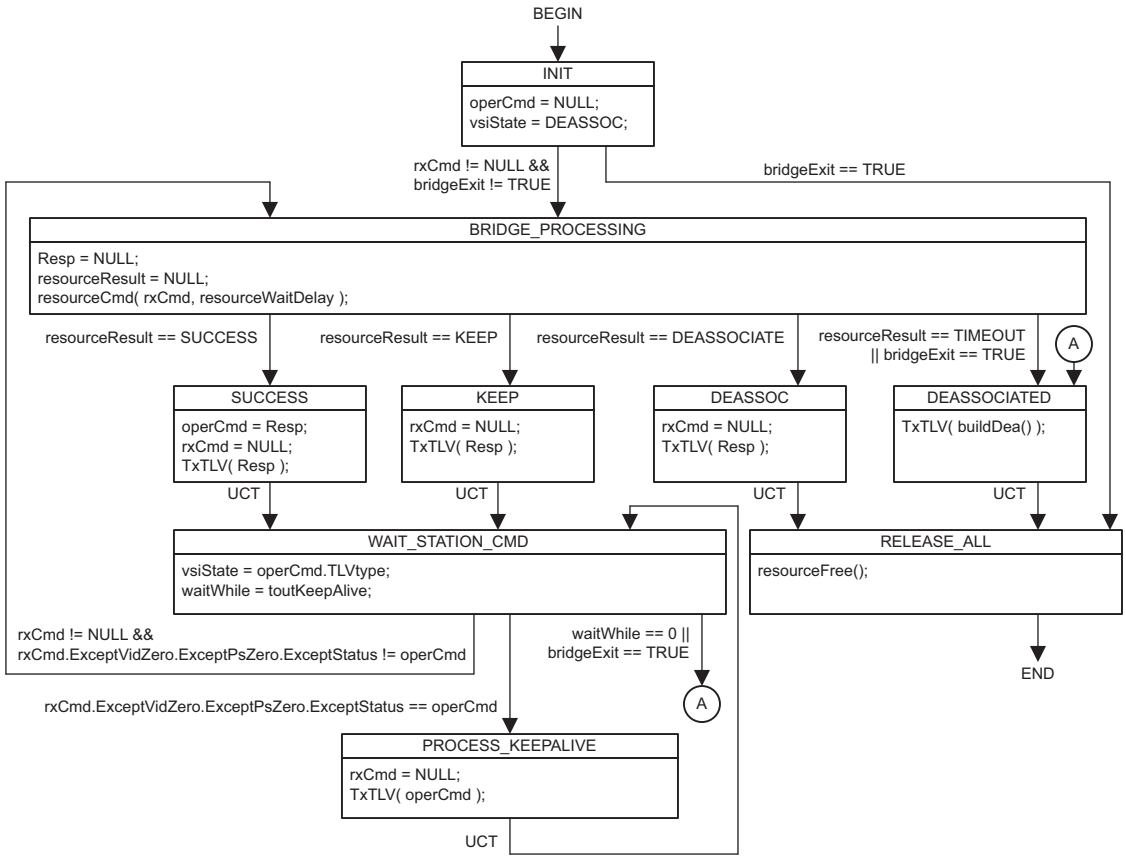

Figure 41-12—Bridge VDP state machine

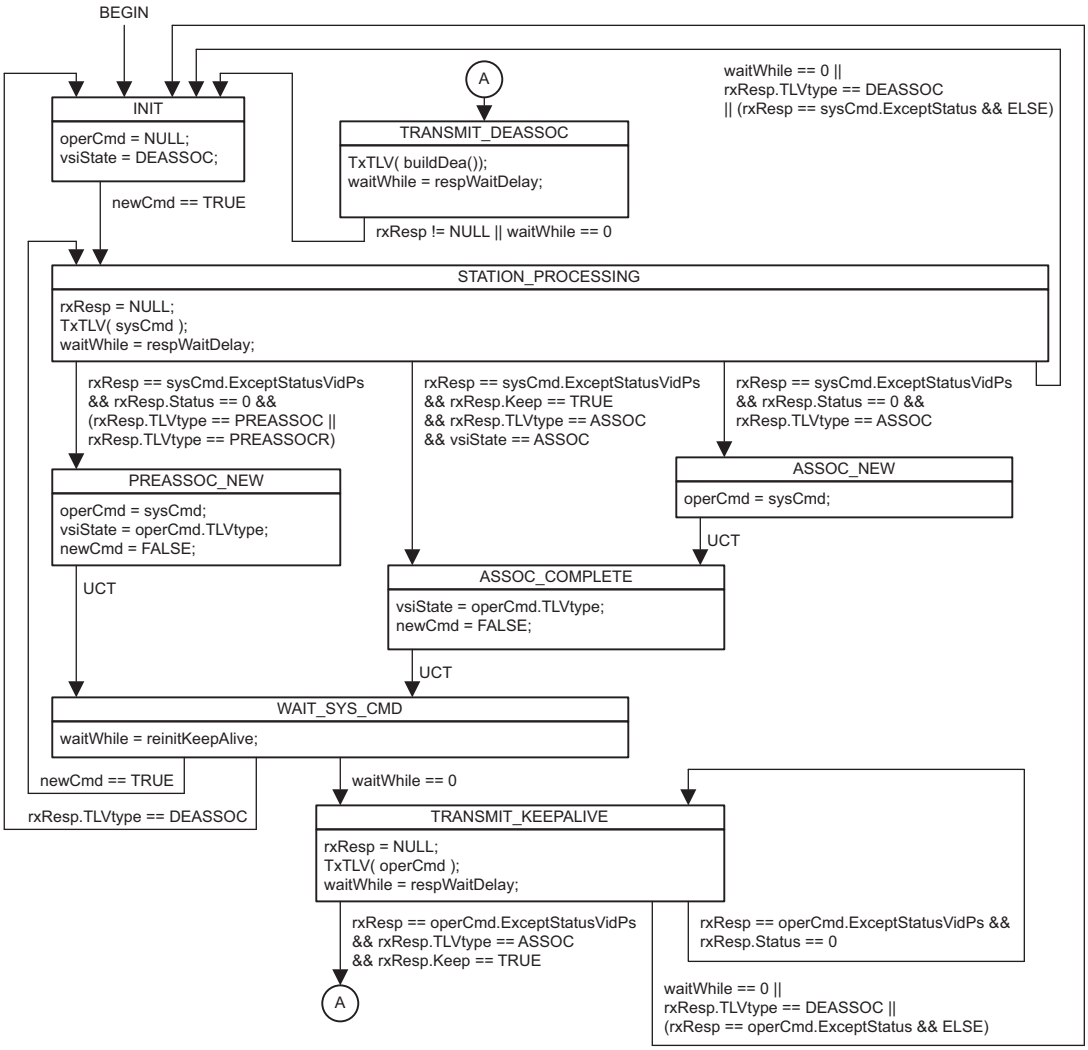
41.5.3 Station VDP state machine

The station VDP state machine shall implement the function defined in Figure 41-13 and the attendant definitions in 41.5.4 through 41.5.7.



NOTE - The ".Except" notation used in some exit conditions is described in 41.5.6.
In this state machine, "ExceptStatus.ExceptVidZero.ExceptPsZero" has been abbreviated to "ExceptStatusVidPs".

Figure 41-13—Station VDP state machine

41.5.4 VDP state machine timers

A set of timers is used by the VDP state machines; these operate as countdown timers (i.e., they expire when their value reaches zero). These timers are 32-bit countdown timers. They:

a) Have a resolution of ten microseconds, with a tolerance of ± 20%.
b) Are started by loading an initial integer value, n, where $0 < n \leq 2^{31}$.
c) Are decremented by one per timer tick, as long as $n > 0$; the interval between timer ticks is the same as the timer resolution.
d) Represent the remaining time in the period.

NOTE—Where timers are used in the VDP state machines to initiate keep-alive messages, it is recommended that a small random component is added to the timer interval in order to avoid the possibility that timers associated with different VSIs become synchronized.

41.5.4.1 waitWhile

An instance of the waitWhile timer exists for each instance of the station VDP state machine (41.5.3) and for each instance of the Bridge VDP state machine (41.5.2).

41.5.5 VDP state machine variables and parameters

41.5.5.1 bridgeExit

A Boolean signal from the Bridge. When TRUE, this variable indicates that the Bridge VDP state machine should exit.

41.5.5.2 newCmd

This variable is set to TRUE by the system to indicate to the state machine that there is a command ready to be transmitted. The state machine sets newCmd FALSE when that command has been processed and is ready to process a further command.

41.5.5.3 NULL

A null value. If NULL is assigned to a TLV variable, it indicates that the variable contains no TLV.

41.5.5.4 operCmd

The command TLV (the TLV that carried the current operating command—associate, pre-associate, or de-associate), at the station or Bridge, or NULL if there is no current operating command.

41.5.5.5 reinitKeepAlive

The value used to initialize the waitWhile timer (41.5.4.1) by the station VDP state machine in order to determine when to transmit a keep alive message. This value is derived from the value of the management variable urpVdpOperReinitKeepAlive (12.26.5), which is type timer exp, by using urpVdpOperReinitKeepAlive as an exponent of 2. The variable urpVdpOperReinitKeepAlive is the larger of the values proposed by the station and Bridge.

The default value used by the station for urpVdpOperReinitKeepAlive is an exponent value of 20, representing a timer interval of about 10.5 s.

41.5.5.6 resourceCmdResult

This variable is used to record the result of a resourceCmd() procedure call (41.5.7.2). The possible result values are as follows:

a) Success
b) timeOut
c) Fail (insufficient resources)
d) Fail (invalid format)
e) Fail (other)

41.5.5.7 resourceWaitDelay

The value used to initialize the waitWhile timer (41.5.4.1) by the Bridge VDP state machine when the state machine is waiting for a response. This value is derived from the values of the management variable sbpVdpOperRsrcWaitDelay (12.26.2), which is type timer exp, by using sbpVdpOperRsrcWaitDelay as an exponent of 2. The variable sbpVdpOperRsrcWaitDelay is the larger of the values proposed by the EVB station and EVB Bridge.

The default value used by the station and Bridge for sbpVdpOperRsrcWaitDelay is an exponent value of 20, representing a timer interval of about 10.5 s.

41.5.5.8 Resp

A response TLV returned from the procedure resourceCmd() (41.5.7.2). Resp can be set to NULL prior to issuing resourceCmd(). The variable is always non-NULL when resourceCmd() completes.

41.5.5.9 respWaitDelay

The value used to initialize the waitWhile timer (41.5.4.1) by the station VDP state machine when the state machine is waiting for a response. This value is derived from the values of the management variables urpVdpOperRsrcWaitDelay (12.26.5), ecpOperAckTimerInit (12.27) and ecpOperMaxRetries (12.27). The value is expressed in units of VDP timer tics of 10 usec by the following equation:

$$\text{respWaitDelay} = 1.5 \times (2^{\text{urpVdpOperRsrcWaitDelay}} + (2 + 2 \times \text{maxRetries}+1) \times \text{ackTimerInit})$$

NOTE 1—The factor of 1.5 allows for a 20% tolerance in the timer values.

where maxRetries is the ECP state machine variable that is ecpVdpOperMaxRetries and ackTimerInit is the ECP state machine variable that is 2ecpOperAckTimerInit. The values of urpVdpOperRscWaitDelay, ecpOperAckTimerInit, and ecpOperMaxRetries that are used are the larger of the values proposed by the station and Bridge.

The default value used by the station and Bridge is about 17.4 s. The default value for urpVdpOperRscWaitDelay is an exponent of 20 representing a timer interval of about 10.5 s and for ecpOperAckTimerInit is an exponent of 14 representing a timer interval of about 164 ms. The default value of the ECP state machine variable ackTimerInit is 16,384 ECP/VDP timer tics. The default value for ecpOperMaxRetries and the ECP state machine variable maxRetries is 3.

NOTE 2—The factor of 1.5 allows for a 20% tolerance in the timer values.

41.5.5.10 rxCmd

The last received command TLV, or NULL if no command TLV has been received. The rxCmd variable is updated only if it is NULL.

41.5.5.11 rxResp

The last received response TLV. The rxResp variable contains the last received Resp TLV at the station or NULL. RxResp is NULL if no TLVs have been received or if the variable has been cleared by the state machine.

NOTE—It is possible to have a race condition when clearing rxResp since it can be updated asynchronously if the Bridge issues an unsolicited DEASSOC command. If the race condition occurs, the de-associate will occur as a result of the station timer expiring.

41.5.5.12 sysCmd

A command TLV from the system or hypervisor, or NULL if there is no pending command. The VDP state machine is ready to accept a new command when the value of sysCmd is NULL.

41.5.5.13 toutKeepAlive

The value used to initialize the waitWhile timer (41.5.4.1) by the Bridge VDP state machine in order to determine when to expect to receive a keep alive message. This variable is derived from the values of the management variables sbpVdpOperReinitKeepAlive (12.26.2), ecpOperAckTimerInit (12.27), and ecpOperMaxRetries (12.27). The value is expressed in units of VDP timer tics of 10 usec by the following equation:

$$\text{toutKeepAlive} = 1.5 \times (2^{\text{sbpVdpOperReinitKeepAlive}} + (2 + 2 \times \text{maxRetries} + 1) \times \text{ackTimerInit})$$

NOTE—The factor of 1.5 allows for a 20% tolerance in the timer values.

Where maxRetries is the ECP state machine variable that is ecpVdpOperMaxRetries and ackTimerInit is the ECP state machine variable that is $2^{\text{ecpOperAckTimerInit}}$. The values of sbpVdpOperReinitKeepAlive, ecpOperAckTimerInit, and ecpOperMaxRetries that are used are the larger of the values proposed by the EVB station and EVB Bridge.

The default value used by the station and Bridge is about 17.4 s. The default for sbpVdpOperReinitKeepAlive is an exponent of 20 representing a timer interval of about 10.5 s and for ecpOperAckTimerInit is an exponent of 14 representing a timer interval of about 164 ms. The default value of the ECP state machine variable ackTimerInit is 16,384 ECP/VDP timer tics. The default value for ecpOperMaxRetries and the ECP state machine variable maxRetries is 3.

41.5.5.14 vsiState

The current association state of the VDP state machine. This variable may take the values DEASSOC (de-associated), PREASSOC (pre-associated), PREASSOCR (pre-associated with resource reservation), or ASSOC (associated).

41.5.6 Command-Response TLV field references in state machines

The state machines can make use of the value of individual fields within the value of a TLV by using the following notation:

Tlv-variable-name.Field-name

In practice, only the following two Field-names are used in the state machines:

a) TLVtype, which references the TLV type field of the TLV (41.2.1)
b) Keep, which references the Keep bit of the Status field in the TLV (41.2.3)

So, for example, a reference in the state diagram to sysCmd.Keep is a reference to the Keep bit of the Status field of the TLV value contained in the sysCmd variable.

The state machines also make use of the ability to compare TLV values for equality or inequality while ignoring a specific field, using the following notation:

Tlv-variable-name.ExceptField-name

This is interpreted as meaning “The value of the TLV contained in the Tlv-variable-name variable, ignoring the value of Field-Name in the comparison.”

The reserved Field-name “VidZero” is used to specify that if any VID in the Filter Info field (41.2.9.1) contains zero, then that VID is ignored in the comparison. The reserved Field-name “PsZero” is used to specify that if PS in the Filter Info field contains zero, then the PS and PCP are both ignored in the comparison.

Multiple fields can be excepted by concatenating ExceptField-name items with a separating period.

The value of the Flag bits (Table 41-2 and Table 41-4) are always ignored in field comparison operations.

41.5.7 VDP state machine procedures

41.5.7.1 buildDea()

The buildDea() procedure builds a DEASSOCIATE TLV for the VSI as the return parameter.

41.5.7.2 resourceCmd(rxCmd, delay)

This procedure makes a resource request from the Bridge, waits for a response, builds a response TLV and places it in the variable Resp. The response values reflect the requested resource action (PREASSOC, ASSOC, or DEASSOC), conditioned by return variable resourceResult, which is set to NULL before calling the resourceCmd procedure and set to one of the following values by the procedure:

a) SUCCESS
b) KEEP
c) DEASSOCIATE
d) TIMEOUT

The response constructed by the procedure in the Resp variable can be PREASSOC, ASSOC, or DEASSOC with a Status, keep indicator and hard error indicator. For a successful completion the procedure will copy the rxCmd parameter into the Resp variable. If the Bridge is selecting VIDs based on GroupIDs, then the procedure also replaces zero VIDs with valid VIDs.

The delay parameter specifies how long the procedure should wait for a response. If the delay is exceeded, no response is received, and the VSI is not associated, then the procedure returns a value of TIMEOUT. If the delay is exceeded, no response is received and the VSI is associated, then the procedure returns a value of KEEP along with a Resp equal to the rxCmd parameter. If the delay is not exceeded, then the procedure returns SUCCESS, KEEP, or DEASSOCIATE depending on the response received along with the rxCmd in the Resp and the Status set as follows:

e) **DEASSOC**:

The procedure returns DEASSOCIATE along with Resp.Status set to Success.

f) **PREASSOC**:
   1) If the request can be satisfied, the procedure returns SUCCESS along with Resp.Status set to Success.
   2) If the request cannot be satisfied, the procedure returns DEASSOCIATE along with Resp.Status set to a code other than Success and the Resp.hard set to TRUE if a retry will not change the situation or FALSE if a retry might change the situation.

g) **PREASSOCR**:
   1) If the request can be satisfied, and the resources requested are available and reserved for this VSI, the procedure returns SUCCESS along with the Resp.Status set to Success.
   2) If the request cannot be satisfied, or the resources are unavailable or not reserved for this VSI, the procedure returns DEASSOCIATE along with the Resp.Status code other than Success and the Resp.hard set to TRUE if a retry will not change the situation or FALSE if a retry might change the situation.

h) **ASSOC**:
   1) If the request can be satisfied, and the resources requested are available and enabled for this VSI, the procedure returns SUCCESS along with the Resp.Status set to Success.
   2) If the request cannot be satisfied, or the resources are unavailable or not reserved for this VSI, and the VSI is not currently Associated, the procedure returns DEASSOCIATE along with the Resp.Status code other than Success and the Resp.hard set to TRUE if a retry will not change the situation or FALSE if a retry might change the situation.
   3) If the request cannot be satisfied, or the resources are unavailable or not reserved for this VSI, and the VSI is currently Associated, the procedure returns KEEP along with the Resp.Status code other than Success and the Resp.hard set to TRUE if a retry will not change the situation or FALSE if a retry might change the situation.

NOTE—A de-associate can happen at any time, initiated by either party to an association.

41.5.7.3 resourceFree()

The resourceFree() procedure frees all resources associated with this VSI.

41.5.7.4 TxTlv(tlv)

The TxTlv() procedure causes the TLV passed in the tlv parameter to be transmitted.

42. S-Channel Discovery and Configuration Protocol (CDCP)

This clause provides an overview, detailed semantics, and state machines for CDCP.

42.1 CDCP discovery and configuration

CDCP is used to configure S-channels (see 40.2). S-channels are implemented in stations and Bridges using a Port-mapping S-VLAN component (22.6.4). Figure 40-1 illustrates the use of S-channels.

When the Port-mapping S-VLAN components used to create S-channels exist, they can exchange un-S-tagged frames that are assigned to S-VID 1 and are considered to be assigned to the default S-channel, which has an S-channel Identifier (SCID) of 1. The default S-channel is always un-S-tagged even when S-channels are enabled.

NOTE 1—SCIDs are locally assigned identifiers.

The S-channel configuration is determined by the Bridge's capabilities and by requests made using CDCP described in this clause. The station requests S-channels using CDCP. CDCP in turn uses an LLDP TLV exchange to coordinate the creation and deletion of S-channels. The LLDP database used by CDCP is addressed using the Nearest non-TPMR Bridge address. The Port-mapping S-VLAN component filters both the Nearest Bridge and the Nearest non-TPMR Bridge addresses on all ports and passes the Nearest Customer Bridge address.

The SCID value 1 and S-VID value 1 are always reserved for the exclusive use as the un-S-tagged default S-channel. CDCP reports the default S-channel in the CDCP TLV as the first SCID, S-VID pair (i.e., <1,1>). The Bridge shall not assign this S-VID except to the default S-channel.

NOTE 2—For the default S-channel, any QoS information that is necessary is extracted from the PCP bits of the C-tag.

42.2 CDCP state machine overview

CDCP requires each side of the configuration be assigned a role as a Bridge or a station. This is done by setting the AdminRole variable. In most cases the station or Bridge role will not be settable, though the protocol allows for systems that can take either role. For CDCP to configure an S-channel, one side takes the station role and the other side takes the Bridge role. If both sides of the LAN have equipment configured as stations or as Bridges the protocol will not configure S-channels.

NOTE—The role adopted by a given system can be fixed if the system is only capable of operating in a given role.

The CDCP state machine (Figure 42-1) operates on data contained in LLDP MIBs that is updated as a result of the reception of CDCP TLVs, exchanged using LLDP operating on the Nearest non-TMPR Bridge address. The structure of CDCP TLVs is defined in D.2.13.

The configuration proceeds by the Bridge providing the best match it can to the station's requested channels and configuration. The station makes the resource request, the Bridge responds with its best matching resources, the station then goes operational and reports its running configuration to the Bridge, and finally the Bridge goes operational with the running configuration of the station.

In the event the station wishes to change its configuration it alters the request in its CDCP TLV and then follows the same process as previously stated. If the 'B' loses its ability to support the current configuration it can alter the current configuration in its CDCP TLV at which time the station drops down to the resources supplied by the Bridge.

42.3 CDCP configuration state machine

The notational conventions used in the specification of CDCP are as stated in Annex E.

In an implementation that supports the station role, the CDCP configuration state machine shall implement the function specified by the state diagram in Figure 42-1 and the attendant definitions in 42.4 and 42.5.

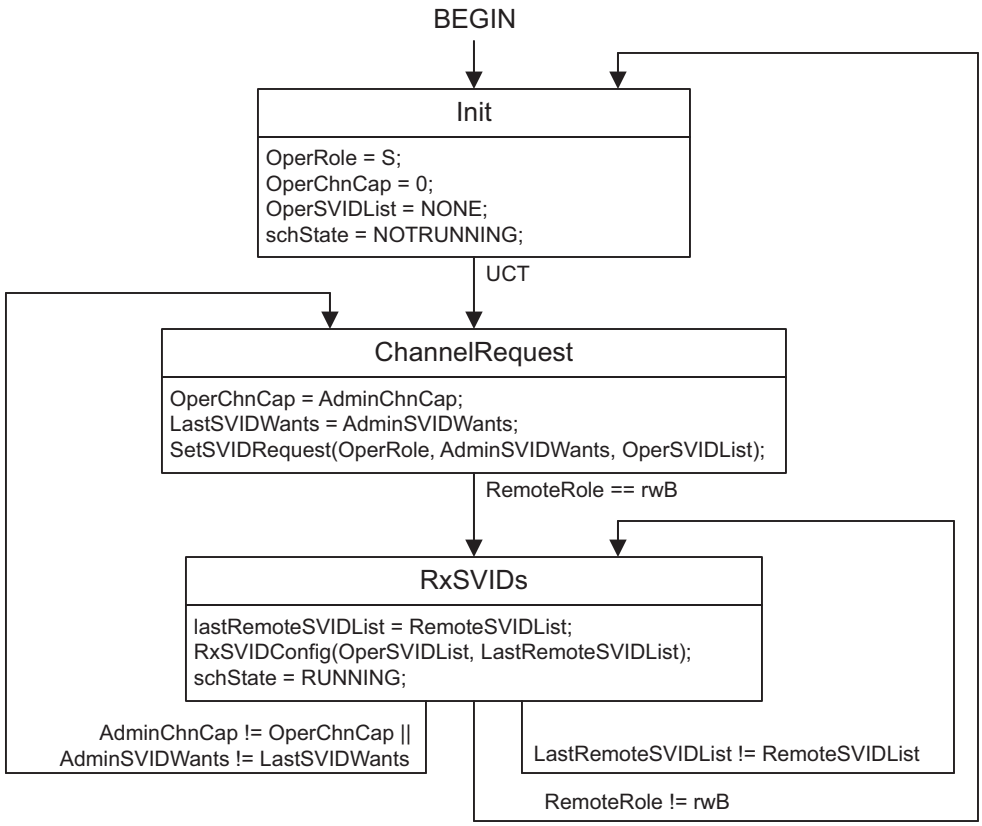


Figure 42-1—CDCP state machine—Station role

In an implementation that supports the Bridge role, the CDCP configuration state machine shall implement the function specified by the state diagram in Figure 42-2 and the attendant definitions in 42.4 and 42.5.

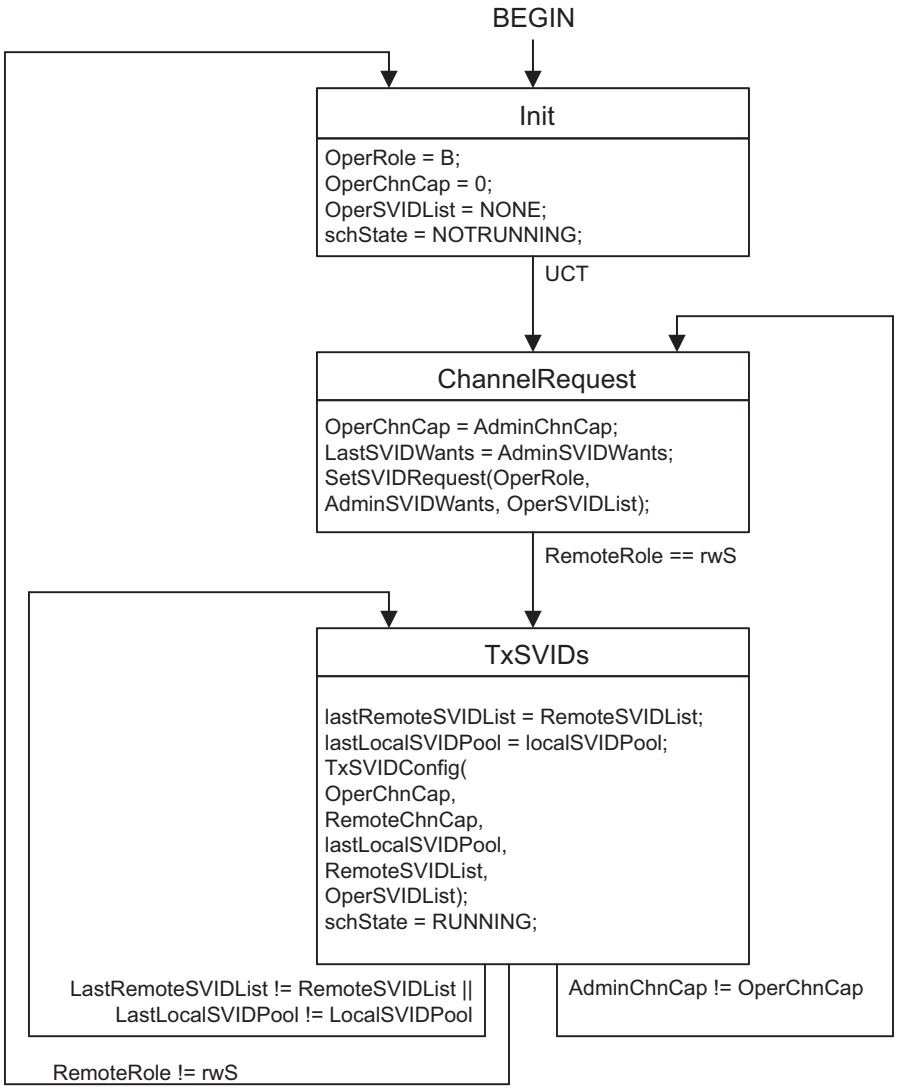

Figure 42-2—CDCP state machine—Bridge role

42.4 CDCP configuration variables

42.4.1 AdminChnCap

The administratively configured value for the Number of Channels supported parameter. This value is included as the ChnCap parameter in the CDCP TLV.

42.4.2 AdminRole

The administratively configured value for the local port's role parameter. The value of AdminRole is not reflected in the CDCP TLV. The AdminRole can take the value S or B; the value determines which of the CDCP state machines is instantiated. If AdminRole is S, the Station role state machine (Figure 42-1) is instantiated. If AdminRole is B, the Bridge role state machine (Figure 42-2) is instantiated. S indicates the sender is unwilling to accept S-channels configuration (mode, number of channels supported, channel index) from its neighbor and that the sender is willing to accept S-VID assignments from the neighbor. Stations usually take the S role. B indicates the sender is willing to accept S-channels configuration (mode, number of channels supported, channel index) from its neighbor and that the sender is willing do the best it can to fill the S-VID requests from the neighbor. Bridges usually take the B role.

42.4.3 AdminSVIDWants

The administratively configured value for (SCID, S-VID) pairs wanted by a station; it is not used by a Bridge. The first value is always the pair (1, 1) for the default S-channel assignment. The S-channel numbers may be any valid number in the range 0–167. A 0 S-channel number indicates reserved space in the TLV. If the S-VID value is 0 it means the station is requesting any available S-VID. S-VID value 1 is reserved for exclusive use for the default S-channel S-VID. No other values of the SVID are permitted. The AdminSVIDWants parameter is used to form the (SCID, S-VID) pairs in the CDCP TLV. This list is formed from the EVB station's S-channel interface table (12.26.4) and is used to build the EVB Bridge's S-channel interface table.

42.4.4 LastLocalSVIDPool

A temporary copy of the LocalSVIDPool.

42.4.5 LastRemoteSVIDList

Temporary local copy of the RemoteSVIDList. This variable is not included in the CDCP TLV. The LastRemoteSVIDList has the same syntax as RemoteSVIDList.

42.4.6 LastSVIDWants

A local temporary copy of the AdminSVIDWants.

42.4.7 LocalSVIDPool

The set of S-VIDs and Bridge Ports available for S-channel assignment. These are determined by both administrative resource assignments and by resource availability. The OperSVIDList for a B role is drawn from the LocalSVIDPool.

42.4.8 OperChnCap

The current value for the ChnCap parameter. This value is included as the ChnCap parameter in the local CDCP TLV. The range for this variable is 1–167.

42.4.9 OperRole

The current operational value of the Role parameter in the local port. This value is included as the Role parameter in the CDCP TLV and may take values S or B as described for AdminRole.

42.4.10 OperSVIDList

The current value for (SCID, S-VID) assignments. This is the list of (SCID, S-VID) pairs included in the local CDCP TLV. The total size of the list cannot exceed 167 pairs. The list always includes the default S-channel pair (1,1).The valid range for each S-channel of this list is from 1–167. The valid range for each S-VID in the list is from 0 to 0xffe. For the S role a S-VID of 0 indicates a request for a channel. For the B role an S-VID of 0 indicates a non-configured channel.

42.4.11 RemoteChnCap

The current value for the ChnCap parameter. This value is included as the ChnCap parameter in the remote CDCP TLV. NULL means no remote CDCP TLV exists in the local LLDP database. The range for this variable is 1–167.

42.4.12 RemoteRole

Indicates the value in the remote CDCP TLV role field. rrNull indicates either the TLV was not present in the last LLDPDU or that no LLDPDUs have been received. rwS and rwB indicate that the Role field was set in the CDCP TLV received and that it had a value of S or B, respectively, as described for the AdminRole variable.

42.4.13 RemoteSVIDList

The current value for (SCID, S-VID) assignments. This is the list of (SCID, S-VID) pairs included in the remote CDCP TLV. NULL means no remote CDCP TLV exists in the local LLDP database. If the list is empty but the CDCP TLV is present, its value is NONE. The total size of the list cannot exceed 167 pairs. The valid range for each S-channel of this list is from 1–167. The valid range for each S-VID in the list is from 0 to 0xffe. When the S-VID is value is 0 the S-VID is not configured. For the S role, a S-VID of 0 indicates a request for a channel. For the B role, an S-VID of 0 indicates a non-configured channel. The RemoteSVIDList is reflected within the EVB Bridge in the S-channel interface table (12.26.4).

42.4.14 schState

The current running state of the S-channel. The values for this variable are NOTRUNNING or RUNNING. This variable can be read using the management functionality defined in Clause 12.

42.5 CDCP configuration procedures

42.5.1 SetSVIDRequest (OperRole, AdminSVIDWants, OperSVIDList)

This function creates the OperSVIDList placed in the Local LLDP database, as follows:

a) If the OperRole for the equipment is B, then the OperSVIDList remains unchanged.
b) If the OperRole for the equipment is S, the function compares the AdminSVIDWants with the OperSVIDList and amends the OperSVIDList, as follows:
    1) All active S-channels in the OperSVIDList that are in the AdminSVIDWants are kept active, and in addition, any channels not currently in the OperSVIDList are requested by including them in the OperSVIDList along with a 0 S-VID number. The OperSVIDList S-channel order is changed to match the AdminSVIDWants.
    2) Any S-channels in the OperSVIDList that are not in AdminSVIDWants are made inactive and are removed from the OperSVIDList.

42.5.2 RxSVIDConfig (OperSVIDList, LastRemoteSVIDList)

This function creates the OperSVIDList placed in the Local LLDP database for an S role port.

The function compares the AdminSVIDWants with the LastRemoteSVIDList. For each AdminSVIDWants S-channel with an S-VID assignment in the LastRemoteSVIDList, a (SCID, S-VID) pair is generated in the OperSVIDList. For each AdminSVIDWants S-channel without an S-VID assignment in the LastRemoteSVIDList, a (SCID,0) pair is generated in the OperSVIDList. The OperSVIDList S-channel order is set to match the AdminSVIDWants.

42.5.3 TxSVIDConfig (OperChnCap, RemoteChnCap, LastLocalSVIDPool, RemoteSVIDList, OperSVIDList)

This function creates the OperSVIDList placed in the Local LLDP database for a B role port.

First the function takes the smaller of the OperChnCap and RemoteChnCap and truncates the RemoteSVIDList to the smaller of the two.

A new OperSVIDList is created as follows:

a) For each S-channel in the RemoteSVIDList with a (SCID, S-VID) pair in the OperSVIDList, the (SCID, S-VID) remains unchanged unless the S-VID is no longer part of the LastLocalSVIDPool. If the S-VID is no longer in the pool, a new one is selected if available. If no S-VID is available, the (SCID, S-VID) pair will be deleted from the OperSVIDList.
b) For each S-channel in the OperSVIDList without a (SCID, SVID) pair in the RemoteSVIDList, the (SCID, SVID) pair will be deleted from the OperSVIDList.
c) For a (SCID, SVID) pair in the remote list, where the S-VID is zero, an S-VID is assigned if it is available and the pair is inserted in the OperSVIDList. If an S-VID is not available, the pair is not inserted in the OperSVIDList.
d) For a (SCID, SVID) pair in the remote list, where the S-VID is nonzero, there is no effect on the OperSVIDList.

43. Edge Control Protocol (ECP)

This clause provides an overview, detailed semantics, and state machines for ECP.

43.1 ECP operation

Figure 43-1 depicts, at a high level, ECP operation. In step 1, the upper layer protocol (ULP) passes an outgoing ULP Data Unit (ULPDU) to ECP by invoking a transmit request procedure. In step 2, the ULPDU, which for some ULPs (e.g., VDP) may contain a set of ULP TLVs, is transmitted and an ECP low-level acknowledgment (ACK) timer is set. The frame is not yet deleted from the transmit buffer until an ACK (L-ACK in the diagram) is received for that ECPDU. In step 3, the arriving ECP frame is received into a receive buffer, where it is held until it is removed by an ECP indication procedure that passes the ULP Data Unit to the associated upper-level protocol. In step 4, when the receive buffer is emptied, a L-ACK is sent to the sender. In step 5, if the L-ACK is received before the L-ACK timer expires, then the transmit buffer is cleared and ECP can process another ULPDU through the ECP procedure. However, if the L-ACK timer expires before the L-ACK is received, then the frame in the transmit buffer is re-sent and the L-ACK timer is re-initialized. This timeout and re-sending can occur up to a maximum number of retries determined by the value of the *maxRetries* parameter of the transmit state machine. If this number of retries is reached and there is still no response, then the transmit buffer is cleared, a failure counter is incremented, and the transmit state machine is then ready to process another ULPDU. There is no indication to the ULP that a transmission failure has occurred; it is the ULP's responsibility both to detect the failure condition and to recover from it in an appropriate way.

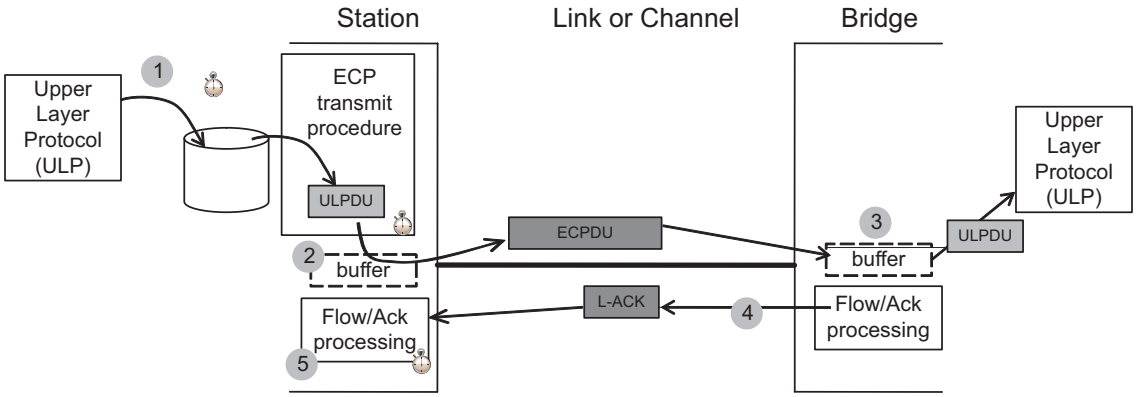

Figure 43-1—Example ECP exchange

ECP is intended to operate between two peers over an IEEE 802 LAN. ECP delivers the following service characteristics:

a) Reliable delivery of ULPDUs, resilient against frame loss. The value of the *maxRetries* parameter determines the number of sequential lost frames that the protocol can sustain.
b) Delivery of ULPDUs to the recipient ULP in the order that they were transmitted by the sending ULP.
c) Delivery of a single copy of each ULPDU to the recipient.
d) Flow control that provides protection against buffer overrun on the receive side.

43.2 Edge Control Sublayer Service (ECSS)

Two service primitives model the hand-off of data units between the ULP and ECP: ECP_UNITDATA.request and ECP_UNITDATA.indication.

ECP_UNITDATA.request (ulptype, ulpdu)

The ECP_UNITDATA.request primitive is invoked by the ULP to notify ECP that a ULPDU is ready to be transmitted. The **ulpdu** parameter is the ULPDU that the ULP wishes to transmit. The **ulptype** parameter identifies the type of the ULP (see 43.3.3).

NOTE—For example, for VDP the ULPDU consists of a set of VDP TLVs passed to ECP for transmission. The maximum size of the ULPDU, and therefore the set of TLVs that it can contain, is determined by the maximum SDU size supported by the underlying MAC (see 6.5.8).

ECP_UNITDATA.indication (ulptype, ulpdu)

The ECP_UNITDATA.indication is invoked by ECP to indicate a ULPDU has been received and is available for ULP processing. The **ulpdu** parameter is the ULPDU that has been received. The **ulptype** parameter identifies the type of the ULP, as indicated in the received ECPDU (see 43.3.3).

43.3 ECP state machines

43.3.1 State machine conventions

The notational conventions used in the specification of ECP are as stated in Annex E.

43.3.2 Overview

There are two state machines used by each ECP instance: the ECP transmit state machine (43.3.4) and the ECP receive state machine (43.3.5). A Bridge Port that supports ECP shall support one instance of the ECP transmit state machine and one instance of the ECP receive state machine.

Initialization of the transmit and receive state machines occurs when portEnabled (43.3.7.5) is FALSE, or when a BEGIN global event occurs. The transmit state machine transmits an ECPDU in response to an ECP_UNITDATA.request from the ULP that indicates there is a PDU ready to be transmitted. The PDU is transmitted with a sequence number that is used by the (remote) receive state machine in a responding ACK ECPDU. If no ACK with the correct sequence number is received within a defined time period, and if the maximum number of retries has not been reached, the transmit state machine retransmits the ECPDU. If the maximum number of retries is exceeded, or if an ACK is received that matches the last sequence number sent, then the transmit state machine increments the sequence number and waits for the next ECP_UNITDATA.request.

NOTE—The sequence number for the first ECPDU transmitted after a state machine initialization (which occurs when BEGIN is TRUE or portEnabled [43.3.7.5] is FALSE) is an implementation choice; for example, it could be a pre-determined number, a random number, or it could continue the sequence from the last sequence number used.

When the first ECPDU is received following initialization, the receive state machine initializes its local record of the last sequence number received to be one less than the sequence number in the received ECPDU. This record of the last sequence number received allows the state machine to detect whether the received ECPDU has been received already (current and last sequence numbers match) or this is a new ECPDU (current and last sequence numbers differ). In both cases, the receive state machine sends an ACK ECPDU, using the current sequence number. In the case that the received ECPDU is new, the last received sequence number is updated to reflect the sequence number of the received ECPDU, and an ECP_UNITDATA.indication is sent to the ULP to pass the contents of the ECPDU to the service user.

43.3.3 Edge Control Protocol Data Unit (ECPDU)

This subclause specifies the format of a ECPDU, along with the header that is added to and removed from ECP frames by the ECP function. The ECP header allows each ECPDU from the sender to be identified through a sequence number, which the receiver acknowledges by sending a ECP Acknowledgment frame. The format of the ECPDU is illustrated in Figure 43-2.

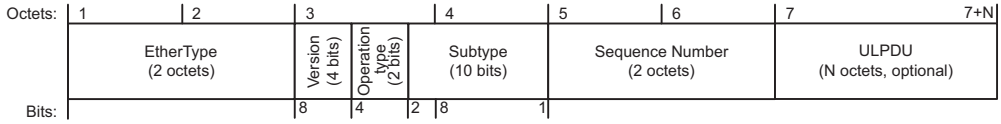

Figure 43-2—ECPDU structure

The destination address of the Ethernet frame that contains a ECPDU is specified by the ULP. The address used is either an individual MAC address or one of the reserved addresses specified in Table 8-1.

The source address shall be the individual MAC address of the sending station or port.

The fields of the ECPDU are defined in the following subclauses.

43.3.3.1 EtherType

A 16-bit field that contains the EtherType assigned for use by ECP (89-40).

43.3.3.2 Version

A 4-bit field that identifies the protocol version. The version shall be 0x01.

43.3.3.3 Operation type

A 2-bit field that identifies the operation type as follows:

a) ECP request (0x0)
b) ECP acknowledgment (0x1)

43.3.3.4 Subtype

A 10-bit field that defines the ULP type included in the PDU. For ACKs the subtype is ignored at the station. The subtype used by VDP is as shown in Table 43-1.

Table 43-1—ECP subtypes

Use	Reference	Subtype
VDP	Clause 41	0x0001
Port Extender Control and StatusProtocol (PE CSP)	IEEE Std 802.1BR	0x0002
Link-local Registration Protocol (LRP)	IEEE Std 802.1CS	0x0003
Reserved for future standardization	—	All other values

43.3.3.5 Sequence Number

A 2-octet field that identifies the sequential order of the PDU, with respect to other ECPDUs. The starting sequence number can start anywhere for the first ECPDU, but the sequence number for each subsequent new request ECPDU is incremented by 1 modulo 65536.

NOTE—The sequence numbers used by each instance of the ECP transmit state machine are independent of each other.

43.3.3.6 ULPDU

This field contains an upper layer protocol data unit (ULPDU) if the operation type in the Mode field is ECP request; the field is absent if the operation type is ECP acknowledgment.

43.3.4 ECP transmit state machine

The ECP transmit state machine shall implement the function specified by the state diagram in Figure 43-3 and the attendant definitions in 43.3.6 through 43.3.8.

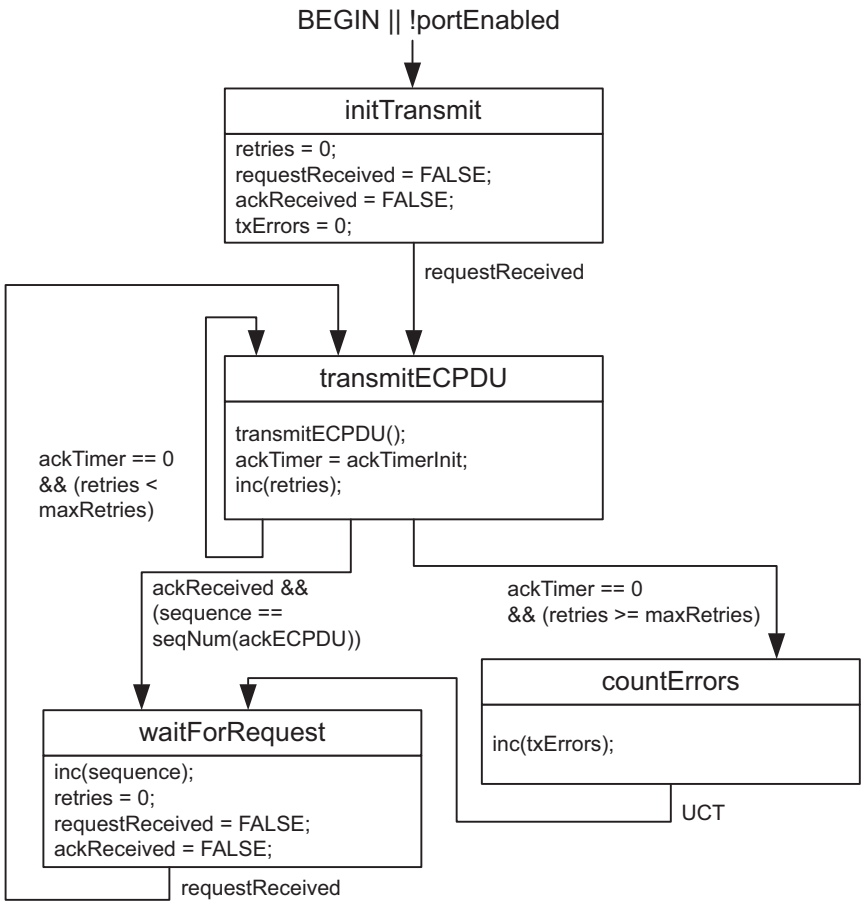

Figure 43-3—ECP transmit state machine

43.3.5 ECP receive state machine

The ECP receive state machine shall implement the function specified by the state diagram in Figure 43-4 and the attendant definitions in 43.3.6 through 43.3.8.

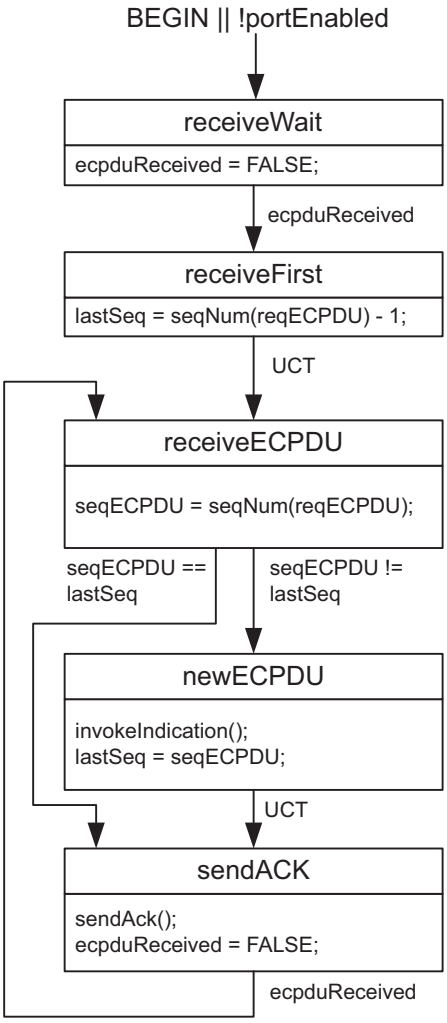

Figure 43-4—ECP receive state machine

43.3.6 ECP state machine timers

A set of timers is used by the ECP state machines; these operate as countdown timers (i.e., they expire when their value reaches zero). These timers are based on the Timer Exp data type (12.3). They:

a) Have a resolution of ten microseconds, with a tolerance of ± 20%.
b) Are started by loading an initial integer value, n, where $0 < n \leq 2^{31}$.
c) Are decremented by one per timer tick, as long as $n > 0$; the interval between timer ticks is the same as the timer resolution.
d) Represent the remaining time in the period.

43.3.6.1 ackTimer

The ackTimer is used to determine how long the transmit state machine will wait for an acknowledgment PDU to be received before it either retries a transmission or aborts a transmission due to too many retries. This timer is initialized using the value of ackTimerInit determined as stated in D.2.12.6.

43.3.7 ECP state machine variables and parameters

43.3.7.1 ackReceived

This Boolean variable is set to TRUE when an ECPDU is received with a MODE field indicating that the PDU is an ACK. The variable is set FALSE by the ECP transmit state machine once the ACK has been processed.

43.3.7.2 ecpduReceived

This Boolean variable is set to TRUE when an ECPDU is received with a MODE field indicating that the PDU is a request. The variable is set FALSE by the ECP receive state machine once the request has been processed and the ACK has been sent.

43.3.7.3 lastSeq

This integer variable is used to record the previous received sequence number.

43.3.7.4 maxRetries

This integer variable defines the maximum number of times that the ECP transmit state machine will retry a transmission if no ACK is received. The default value of maxRetries is 3; this variable can be changed by management as documented in 12.26.2. The value is derived from ecpOperMaxRetries (Table 12-31).

43.3.7.5 portEnabled

This Boolean variable is set to the value of the MAC_Operational parameter (IEEE Std 802.1AC) for the Port.

43.3.7.6 requestReceived

This Boolean variable is set to TRUE when a ULP issues an ECP_UNITDATA.request primitive. The variable is set FALSE by the state machine once the request has been processed.

43.3.7.7 retries

This integer variable counts the number of transmission retries that have been made for the current ECPDU.

43.3.7.8 seqECPDU

This integer variable is used to record the sequence number contained in the most recent received request ECPDU.

43.3.7.9 sequence

This integer variable is used to record the current sequence number that is used in transmitted request ECPDUs.

43.3.7.10 txErrors

This integer variable is used to count the number of times that the ECP transmit state machine has retransmitted an ECPDU.

43.3.8 ECP state machine procedures

43.3.8.1 inc(counter)

This procedure increments the counter variable by 1 modulo 65 536.

43.3.8.2 transmitECPDU()

This procedure causes an ECPDU to be transmitted, using the PDU structure defined in 43.3.3. The sequence number field is set to the least significant 16 bits of the current sequence number contained in the sequence variable (43.3.7.9). The mode field is set to ECP request. The ULPDU field is set to the value of the ulpdu parameter of the request primitive. The subtype field is set to the value of the ulptype parameter of the request primitive.

43.3.8.3 invokeIndication()

This procedure causes an ECP_UNITDATA.indication primitive to be invoked in order to pass the contents of an incoming ECPDU to the ECP service user. The ulptype parameter carries the value of the ULP type carried in the ECPDU. The ulpdu parameter carries the value of the ULPDU field of the ECPDU.

43.3.8.4 sendAck()

This procedure causes an ECPDU to be transmitted, using the PDU structure defined in 43.3.3. The sequence number field is set to the least significant 16 bits of the sequence number contained in the seqECPDU variable (43.3.7.8). The mode field is set to ECP acknowledgment. The ULPDU field is absent. The subtype field is set to the value of the ulptype parameter of the received request ECPDU.

43.3.8.5 seqNum(pdu-type)

This procedure returns an integer value equal to the value of the most recently received request ECPDU (pdu-type = reqECPDU) or acknowledgment ECPDU (pdu-type = ackECPDU).

44. Equal Cost Multiple Paths (ECMP)

SPB supports two approaches to spreading traffic load. The first approach, ECT VLANs, spreads traffic by assigning each service instance to a VLAN configured to use one of the supported SPT Sets. This approach is applicable to both SPBV and SPBM. Each Base VID is assigned to an ECT-ALGORITHM (tie-breaker) that defines the SPT Set for that VLAN, and different ECT Algorithms may thus be used to select different shortest paths in the SPT Region. In case of a PBBN, each I-SID is assigned to a Base VID. This approach can spread traffic load while maintaining traffic path congruence in each VLAN.

The second approach, ECMP, spreads traffic by employing multiple equal cost paths with a single VID. This approach is applicable only to SPBM. Unicast frame filtering dynamically selects a next hop from the set of equal cost next hops for the frame's destination MAC address. Multicast frame filtering is controlled by selecting a multicast routing mode and a tie-break mask for each backbone service instance and advertising that selection in ISIS-SPB. Multicast filtering entries for the backbone service instance are generated by calculations that select a multicast tree from the set of Equal Cost Trees (ECTs) in the SPT Region based on the advertised multicast mode and tie-break mask.

44.1 SPBM ECMP

44.1.1 ECMP Operation

SPBM ECMP provides a mechanism to spread traffic load across a set of equal cost shortest paths in an SPT Region using a single VID. Rather than using one equal cost tie-breaking function to create a single SPT for all individual addresses, ECMP uses a hash function to spread individual address forwarding over a set of equal cost forwarding ports.

If flow filtering (44.2) is not supported, the ECMP ECT Algorithm selects one port from the set of equal cost forwarding ports for each individual address (44.1.2) and creates a Dynamic Filtering Entry for the address indicating the selected port.

If flow filtering (44.2) is supported, a set of equal cost forwarding ports may be recorded in the FDB in a Dynamic Filtering Entry (8.8.3). During unicast frame filtering the MAC Relay Entity selects one forwarding port from the applicable set using a dynamic port selection process (44.2.3).

The individual address forwarding port selection processes, both with and without flow filtering, are designed to:

a) Spread traffic (i.e., make varied choices) for different flows traversing the SPT Region, and
b) Maintain frame ordering for each flow by making the same choice for all frames belonging to any single flow.

ECMP is supported by Dynamic Filtering Entries in the FDB and, optionally, the flow filtering tag (F-TAG, 44.2.1) that carries Flow Hash and TTL information. The flow hash serves both to distinguish frames belonging to different flows and to identify frames that belong to (or may belong to) the same flow. The flow hash is used as input to the dynamic port selection process to support the design goals noted above. The TTL is used to mitigate traffic loops, if they happen to occur (44.2.4).

While unicast frames are spread across equal cost paths, multicast frames cannot be treated this way. Instead multicast traffic load is spread by assigning a multicast mode and tie-breaker to each group address. This selection enables the use of varied SPTs for each group address or set of group addresses. The default ECMP ECT Algorithm selects a source rooted SPT for each node that may transmit multicast traffic. This default source rooted SPT is used for all group addresses assigned to that node. Finer grained control of multicast load spreading is done by selecting a multicast mode and tie-break mask for a particular I-SID. This

selection governs the multicast routing used for that I-SID's assigned group address. The selectable multicast modes include the following:

c) Source rooted SPT
d) Shared tree
e) Head-end replication

Up to 16 source rooted SPTs can be supported per node by using one of 16 different tie-break masks in calculating the SPT. During SPT calculation the tie-break mask is used to select one from the set of equal cost parents (neighbor nodes closer to the root) for each node (28.9). The default multicast treatment is equivalent to using a tie-break mask of zero. An I-SID on a CBP can be assigned to a specific SPT by configuring the Tie-Break Mask for that I-SID [item h) in 12.25.6.1.2 and item h) in 28.12.10].

To reduce the amount of multicast forwarding state required, shared (spanning) trees are supported. Up to 16 shared trees can be configured using the 16 tie-break masks. For shared trees the tie-break mask is used both to select a shared tree root Bridge and to select from the set of equal cost parents for each node in the tree. The shared tree root for a given tie-break mask is determined by selecting the best (least) masked Bridge ID (i.e., the Bridge ID value masked using the tie-break mask). The SPT calculation from the shared tree root also uses the tie-break mask to select between equal cost parents (again selecting the least masked Bridge ID). Each I-SID on a CBP can be assigned to a shared tree by setting a shared tree transmit indicator bit and configuring the tie-break mask to identify the shared tree (28.12.10). All CBPs for a given I-SID that transmit on a shared tree use the same group address (Figure 27-6), and share the forwarding state for this address in the FDB.

It is possible to avoid using group addresses altogether and handle multicast frames by head-end replication. An I-SID on a CBP using head-end replication sends a unicast frame to each destination instead of sending a group addressed frame. If an I-SID is using head-end replication it is configured to indicate no multicast transmission from that CBP. In this case no group address forwarding state will be installed for that I-SID's assigned address at that CBP (28.9). An I-SID using head-end replication at a CBP should nevertheless indicate that it wishes to receive multicast frames since other CBPs supporting the same I-SID may still use multicast.

NOTE—ISIS-SPB does not check for the use of the same tree type for all endpoints of an I-SID, but use of different tree types within a single I-SID is not recommended.

44.1.2 ECMP ECT Algorithm

The content of FDB entries for individual addresses in ECMP depends on whether flow filtering (44.2) is supported by a Bridge.

If flow filtering is not supported or the ECT-ALGORITHM value indicates no flow filtering (Table 44-1), then for each individual address the ECMP ECT Algorithm selects one port from the set of equal cost forwarding ports using a form of the FNV non-cryptographic hash algorithm and creates a Dynamic Filtering Entry (8.8.3) indicating that port as forwarding. The forwarding port is selected by the following process:
