Revision History

Revision Number	Description	Date
1.0	Initial Release of the document.	March 2021
2.0	Numerous updates across chapters include the following: • Event-related fields in the VMCS are renamed for consistency with FRED. • Changes are made to the event data saved for debug exceptions. • The treatment of event data by VMX transitions is updated and event-data fields are added to VMCS. • The treatment of RPL values by FRED event delivery and ERETS is updated. • FRED event delivery indicates whether event occurred in 64-bit mode. • FRED event delivery clears RFLAGS.TF. • The entry point for events incident to ring 0 is now 256 bytes after that for ring 3. • ERETU clears any earlier monitoring by UMONITOR. • ERETU provides the same instruction-ordering guarantees as SYSRET. • MOV to SS and POP SS do not block events when FRED transitions are enabled. • FRED event delivery of INT1, INT3, INT *n*, INTO, SYSCALL, SYSENTER save the instruction length on the stack. • VMX support for instruction length that already exists for INT1, INT3, INT *n*, and INTO is extended to SYSCALL and SYSENTER. • The addresses in the FRED RSP MSRs must be 64-byte aligned. WRMSR and VM entry will enforce this.	June 2021
3.0	Principal changes: • Previous versions of this specification augmented the existing token-based management of shadow-stack switching with an MSR-based verification mechanism. This version of the specification eliminates the token-based management (and the MSR-based verification) and replaces it with checks by ERETS and ERETU of a FRED SSP MSR. (In addition, ERETU can be executed only if CSL = 0 and FRED event delivery checks the canonicality of the new SSP value.) These changes are reflected in Section 3, Section 4.3, Section 5, Section 6, Section 9, and Appendix A. This also resulted in deletion from Section 7 of a subsection "WRMSR and XRSTORS" that specified details of the MSR-based verification mechanism. • When supervisor shadow stacks are enabled, FRED event delivery within ring 0 pushes the CSL on the shadow stack instead of the CS selector; ERETS compares the stack-level values popped from the regular and shadow stacks and causes #CP if they are not equal. • The format of the 64 bytes pushed on the regular stack by FRED event delivery have been reorganized. Corresponding changes have been made to ERETS and ERETU. FRED event delivery indicates whether the event was a nested exception. • Removed references to the IA32_FMASK MSR; FRED event delivery clears RFLAGS unconditionally. • Existing instructions cannot be used to enter compatibility mode in ring 0 (see Section 7.2). This limitation is also mentioned in Section 3 and resulted in corresponding updates to Section 9.5.2.3 and Section 10. • Deleted a section on "Blocking Due to MOV to SS or POP SS." Enabling FRED transitions does not affect this blocking, which still occurs if those instructions are used. This change resulted in text being deleted from Section 9.5.3 and Section 9.6.1. • LKGS can be executed only in 64-bit mode. With a null selector, the instruction zeroes the IA32_KERNEL_GS_BASE MSR. (Changes continue on next page)	May 2022

Revision Number	Description	Date
3.0	(Changes continued from previous page) Other changes: • Corrected an item in Section 4.3 that misidentified the bits in the IA32_FRED_CONFIG MSR that can be written to modify CSL. (The correct bits are 1:0.) • Clarified in Section 4.3 that the FRED SSP MSRs exist even on CPUs that do not support CET. • Added to Section 5.1.1 an indication that FRED event delivery will lead to a general-protection fault if the new RIP is value is not canonical. • Revised Section 5.1.2 and Section 5.1.3 with regard to the checking and loading of the new SSP value. • In Section 5.2.1, clarified the relations between #DB event data and DR6. • Added a sentence at the end of Section 5.3 to clarify that data breakpoints detected during FRED event delivery may be pending after completion of FRED event delivery. • Updated Section 6.2.1 to specify that ERETU always sets the RPL fields for CS and SS to 3. • Added to Section 8 text clarifying why LKGS clears IA32_KERNEL_GS_BASE[63:32]. • Added to Section 9.3.4 an explanation of why no new VMCS field is added for exiting-event data. • Corrected an item in Section 9.5 that misidentified the bit in the CR4 field in the guest-state area of the VMCS that correspond to the bit in CR4 that enables FRED transitions. (The correct bit is 32.) • Added to an item in Section 9.5.1 a sentence specifying that, if VM entry is injecting SYSCALL or SYSENTER, the VM-entry instruction-length field must be in the range 0–15. Added a footnote to that item, recalling that VM entry can use event type 7 for pending MTF VM exits (as well as SYSCALL and SYSENTER). • Updated the pseudocode in Appendix A.1 as follows: — To align with Section 5.2.1 and indicate that FRED event delivery saves the oldCSL as 0 when delivering an event that occurred in ring 3. — To order the check on the canonicality of the new RIP value to follow the determination of that value. — To clarify the determination of event stack level for privileged software exceptions (INT1). — To clarify that FRED event delivery establishes the pseudovariable newSSP only if supervisor shadow stacks are enabled. If newSSP is loaded from an MSR, it is immediately checked for canonicality and alignment. • In Appendix A.3, removed a check that SSP must be 8-byte aligned.	May 2022

1 Introduction

This document is a specification of the architecture of a new feature called **flexible return and event delivery** (**FRED**).

The FRED architecture defines simple new transitions that change privilege level (**ring transitions**). The FRED architecture was designed with the following goals:

- Improve overall performance and response time by replacing event delivery through the interrupt descriptor table (**IDT event delivery**) and event return by the IRET instruction with lower latency transitions.
- Improve software robustness by ensuring that event delivery establishes the full supervisor context and that event return establishes the full user context.

The new transitions defined by the FRED architecture are **FRED event delivery** and, for returning from events, two **FRED return instructions**. FRED event delivery can effect a transition from ring 3 to ring 0, but it is used also to deliver events incident to ring 0. One FRED instruction (ERETU) effects a return from ring 0 to ring 3, while the other (ERETS) returns while remaining in ring 0.

In addition to these transitions, the FRED architecture defines a new instruction (LKGS) for managing the state of the GS segment register. The LKGS instruction can be used by 64-bit operating systems that do not use the new FRED transitions.

The following is the organization of this specification:

- Section 2 describes the existing behavior of ring transitions in the Intel® 64 architecture.
- Section 3 gives an overview of the FRED architecture.
- Section 4 gives details on enumeration and configuration of FRED, including the new state defined for FRED.
- Section 5 explains FRED event delivery.
- Section 6 presents the FRED return instructions.
- Section 7 describes how enabling FRED transitions changes the operation of existing instructions (including those use for system call and return).
- Section 8 presents a new instruction (LKGS) for managing the state of the GS segment register.
- Section 9 provides details of virtualization support (VMX) for the FRED architecture.
- Section 10 identifies minor changes to the delivery of system-management interrupts and execution of the RSM instruction.
- Appendix A presents details of the operation of FRED event delivery and the FRED return instructions.
- Appendix B provides a supplementary discussion of event stack levels.

Note: This document uses the term **canonical** in two different ways. A linear address is **canonical relative to the processor's maximum linear-address width** if bits 63:M–1 of the address are identical, where M is processor's maximum linear-address width (as enumerated in CPUID.80000008H:EAX[bits 15:8]). A linear address is **canonical relative to the current paging mode** if bits 63:M–1 of the address are identical, where M is 48 if 4-level paging is enabled and 57 if 5-level paging is enabled.

2 Ring Transitions and the CS, SS, and GS Segments

The Intel® 64 architecture's protection architecture is based on use of a 2-bit privilege level (0–3). Operation at a particular privilege level is informally called a **ring**; thus, ring 0 (the most privileged ring) refers to operation while the current privilege level (CPL) is 0, while ring 3 (the least privileged ring) refers to operation while the CPL is 3.

The Intel 64 architecture defines a number of control-flow transitions that change the CPL. Known informally as **ring transitions**, there are two principal types:

- Transitions that increase privilege (by decreasing the CPL). These include transitions using interrupt and trap gates in the interrupt descriptor table (IDT), executions of the far CALL instruction that access call gates, and executions of the SYSCALL and SYSENTER instructions.
- Transitions that decrease privilege (by increasing the CPL). These include executions of the instructions IRET, far RET, SYSEXIT, and SYSRET.

In IA-32e mode, the CPL is visible to software in the RPL field (bits 1:0) of the CS segment selector. In addition, the DPL field in the descriptor cache for the SS segment also contains the CPL, although this is not directly visible to software. Because the CPL is manifest in the CS and SS segment registers, ring transitions always modify the CS and SS segment registers.

GS is another segment that software manages at the time of ring transitions. This is because 64-bit operating systems use the GS segment to support **thread-local storage** (TLS): the GS base address identifies the location of the TLS. User and supervisor software use the TLS at different addresses, so the base address of the GS segment will differ depending on the CPL.

Unlike CS and SS, GS is not modified by existing ring transitions. This means that, after a transition to ring 0, the GS base address will still reference the user TLS. For this reason, supervisor software must update the GS base address before it can access its own TLS. Similarly, it must switch the GS base address back to the user value before returning to user software. The SWAPGS instruction supports efficient updates of the GS base address.

3 Overview of the FRED Architecture

The following items summarize the principle elements of the FRED architecture:

- **FRED event delivery.** Any event that would normally cause IDT event delivery (e.g., an interrupt or exception) will instead establish the new context with a new process that does not access existing data structures such as the IDT. The SYSCALL and SYSENTER instructions will also use FRED event delivery in place of their existing operation.
- **FRED return instructions.** Two new return instructions, ERETS and ERETU, effect simple returns from event handling. ERETS (event return to supervisor) is designed to return from events incident to ring 0 and does not change CPL; ERETU (event return to user) returns to application software operating in ring 3.
- **GS segment management.** FRED transitions that change the CPL (FRED event delivery and ERETU) update the GS base address in a manner similar to the SWAPGS instruction. In addition, the LKGS instruction allows system software to manage the GS segment more flexibly.

When FRED transitions are enabled, they are the only ring transitions possible. Since FRED event delivery is always to ring 0 and ERETU returns only to ring 3, it is not possible to enter ring 1 or ring 2 while FRED transitions are enabled. Enabling FRED transitions also prevents entry to compatibility mode in ring 0.

The FRED architecture is defined for use by a 64-bit operating system. Except where noted, changes to processor behavior and new instructions apply only in IA-32e mode (IA32_EFER.LMA = 1) and not in legacy protected mode (or real-address mode). The new processor state defined by the FRED architecture is accessible with RDMSR and WRMSR regardless of mode.

The FRED architecture introduces the concept of a **stack level**. The **current stack level** (CSL) is a value in the range 0–3 that the processor tracks when CPL = 0. FRED event delivery determines the stack level associated with the event being delivered and, if it is greater than the CSL (or if CPL had been 3), loads the stack pointer (RSP) from a new **FRED RSP MSR** associated with the event's stack level. (If supervisor shadow stacks are enabled, the stack level applies also to the shadow-stack pointer, SSP, which would be loaded from a **FRED SSP MSR**.) The FRED return instruction ERETS restores the old stack level. (Details of the new MSRs are given in Section 4.3.)

The existing shadow-stack architecture includes a token-management mechanism to ensure shadow-stack integrity when switching shadow stacks. This mechanism uses locked read-modify-write operations that may affect worst-case performance adversely. FRED transitions do not use this token-management mechanism and instead protect shadow-stack integrity by having the FRED return instructions check values in the FRED SSP MSRs.

4 Enumeration, Enabling, and Configuration

This section describes the enumeration, enabling, and configuration mechanisms for the FRED architecture.

4.1 Enumeration

The FRED architecture includes two related but independent elements: the new FRED transitions and the LKGS instruction for management of the GS segment register. Because 64-bit operating systems may benefit from the LKGS instruction without using FRED, the two elements are enumerated independently.

CPUID.(EAX=7,ECX=1):EAX.FRED[bit 17] is a new feature flag that enumerates support for the new FRED transitions. It also enumerates support for the new architectural state (MSRs) defined by FRED.

CPUID.(EAX=7,ECX=1):EAX.LKGS[bit 18] is another new CPUID feature flag that enumerates support for the LKGS instruction.

Any processor that enumerates support for FRED transitions will also enumerate support for LKGS.

4.2 Enabling in CR4

Software enables FRED transitions by setting CR4[32] (henceforth CR4.FRED).[1]

FRED transitions are enabled for a logical processor when CR4.FRED = 1 and the logical processor is in IA-32e mode (IA32_EFER.LMA = 1). Specifically, setting CR4.FRED enables FRED event delivery (Section 5) in IA-32e mode. It also enables the FRED return instructions (Section 6), but only in 64-bit mode (when IA32_EFER.LMA = CS.L = 1).

The value of CR4.FRED does **not** affect the accessibility of the new MSRs (Section 4.3) by RDMSR and WRMSR, nor does it effect the operation of the new LKGS instruction (Section 8).

Enabling FRED transitions changes the behavior of various existing instructions. See Section 7.

4.3 New MSRs for Configuration of FRED Transitions

FRED transitions are controlled by the following new MSRs:

- IA32_FRED_CONFIG (MSR index 1D4H). This MSR is organized as follows:
  - Bits 1:0 of this MSR contain the **current stack level** (CSL). This 2-bit value is manipulated and used by FRED event delivery (Section 5) and the FRED return

1. Execution of the MOV to CR4 instruction outside 64-bit mode clears CR4[63:32]. For that reason, software must first enter 64-bit mode before using MOV to CR4 to set CR4.FRED.

instructions (Section 6).

Software can modify the CSL with the WRMSR instruction, but this is not an expected usage. It is recommended that, when using WRMSR to update IA32_FRED_CONFIG, software always write the existing CSL into bits 1:0 of the MSR (unless it specifically desires to change the CSL).

— Bit 2 is reserved.

— Bit 3 indicates, if set, that FRED event delivery should decrement the shadow stack pointer (SSP) by 8 when not changing stacks.

— Bits 5:4 are reserved.

— Bits 8:6 identify the amount (measured in 64-byte cache lines) by which FRED event delivery decrements the regular stack pointer (RSP) when not changing stacks.

— Bits 10:9 identify the stack level that is used for maskable interrupts that are delivered in ring 0. See Section 5.1.2.

— Bit 11 is reserved.

— Bits 63:12 contain the upper bits of the linear address of a page in memory containing event handlers. FRED event delivery will load RIP to refer to an entry point on this page. See Section 5.1.1.

WRMSR to this MSR causes a general-protection exception (#GP) if its source operand sets any reserved bits or if it is not canonical relative to the processor's maximum linear-address width.

- IA32_FRED_RSP0, IA32_FRED_RSP1, IA32_FRED_RSP2, and IA32_FRED_RSP3 (MSR indices 1CCH–1CFH). These are the **FRED RSP MSRs**.

  If FRED event delivery causes a transition from ring 3 or a change to the CSL, it loads RSP from the FRED RSP MSR corresponding to the new stack level. See Section 5.1.2.

  WRMSR to any of these MSRs causes a general-protection exception (#GP) if its source operand is not 64-byte aligned (bits 5:0 are not all zero) or if it is not canonical relative to the processor's maximum linear-address width.

Note: The numbers 0–3 in the MSR names refer to the corresponding stack level **and not to privilege level**.

- IA32_FRED_STKLVLS (MSR index 1D0H). This MSR is interpreted as an array of 32 2-bit values, one for each vector in the range 0–31. For an exception with vector *v* (or for a non-maskable interrupt, which always has vector *v* = 2) that occurs in ring 0, FRED event delivery ensures that the new stack level is at least the value of IA32_FRED_STKLVLS[2*v*+1:2*v*]. See Section 5.1.2.
- IA32_FRED_SSP1, IA32_FRED_SSP2, and IA32_FRED_SSP3 (MSR indices 1D1H–1D3H). Together with the existing MSR IA32_PL0_SSP (MSR index 6A4H), these are the **FRED SSP MSRs**. References in this document to "IA32_FRED_SSP0" are to the IA32_PL0_SSP MSR.

  If supervisor shadow stacks are enabled and FRED event delivery causes a transition from ring 3 or a change to the CSL, it loads SSP from the FRED SSP MSR corresponding to the new stack level. See Section 5.1.2.

  The address in each of IA32_FRED_SSP*i* (1 ≤ *i* ≤ 3) must be 8-byte aligned, so bits 2:0 are reserved. For legacy reasons, IA32_PL0_SSP (IA32_FRED_SSP0) is allowed to be 4-byte aligned, so only bits 1:0 are reserved.

WRMSR to any of these MSRs will cause a general-protection exception (#GP) if its source operand sets any reserved bits or if it is not canonical relative to the processor's maximum linear-address width. (The same is already true for executions of XRSTORS and WRMSR that would load IA32_PL0_SSP.)

Note: As with the FRED RSP MSRs, the numbers 0–3 in the MSR names refer to the corresponding stack level **and not to privilege level**.

Note: The FRED SSP MSRs are supported by any processor that enumerates CPUID.(EAX=7,ECX=1):EAX.FRED[bit 17] as 1. If such a processor does not support CET, FRED transitions will not use the MSRs (because shadow stacks are not enabled), but the MSRs would still be accessible using RDMSR and WRMSR.

The RESET state of each of the new MSRs is zero. INIT does not change the value of the new MSRs.

4.4 FRED Use of Existing MSRs

In addition to the new MSRs identified in Section 4.3, FRED transitions use several existing MSRs as specified in the following items:

- IA32_STAR.
  - Existing use: this MSR is used by the existing operation of SYSCALL and SYSRET.
  - FRED use: FRED event delivery loads the CS and SS selectors with values derived from IA32_STAR[47:32] (see Section 5.3). ERETU uses the value of IA32_STAR[63:48] to determine how to load the CS and SS registers (see Section 6.2.1).

    It is expected that operating systems will set IA32_STAR[33:32] to 00B and IA32_STAR[49:48] to 11B.
- IA32_KERNEL_GS_BASE.
  - Existing use: the SWAPGS instruction exchanges the value of this MSR with the base address of the GS segment register.
  - FRED use: executions of ERETU perform this same swapping operation, as does FRED event delivery of events that arrive in ring 3.
- IA32_PL0_SSP.
  - Existing use: the shadow-stack feature of control-flow enforcement technology (CET) typically loads SSP from this MSR when entering ring 0.
  - FRED use: FRED transitions use this MSR as IA32_FRED_SSP0 (Section 4.3).

5 FRED Event Delivery

When FRED transitions are enabled (CR4.FRED = IA32_EFER.LMA = 1), IDT event delivery of exceptions and interrupts is replaced with **FRED event delivery**. In addition, the existing operation of SYSCALL and SYSENTER is also replaced with FRED event delivery.

These changes do not affect the processor's handling of exceptions and interrupts prior to event delivery. For example, any determination that an event causes a VM exit or is converted into a double fault occurs normally. Similarly, page faults and debug exceptions update CR2 and DR6, respectively, in the normal way.

The principal functionality of FRED event delivery is to establish a new context, that of the event handler in ring 0, while saving the old context for a subsequent return. Some parts of the new context have fixed values, while others depend on the old context, the nature of the event being delivered, and software configuration. Section 5.1 describes how FRED event delivery determines and establishes the new context. Section 5.2 specifies how FRED event delivery saves elements of the old context on the stack (and, when enabled, the shadow stack). Section 5.3 then describes how additional state is updated.

Appendix A.1 presents the detailed flow of the operation of FRED event delivery.

5.1 Determining and Establishing the New Context

The context of an event handler invoked by FRED event delivery includes the CS and SS segment registers, the instruction pointer (RIP), the flags register (RFLAGS), the stack pointer (RSP), and the base address of the GS segment (GS.base). The context also includes the shadow-stack pointer (SSP) if supervisor shadow stacks are enabled.

FRED event delivery establishes this context by loading these registers appropriately. It determines the values to be loaded into RIP, RSP, GS.base, and SSP based on the old context, the nature of the event being delivered, and software configuration. RFLAGS, CS, and SS are loaded with fixed values.

5.1.1 Determining the New RIP Value

FRED event delivery uses two entry points, depending on the CPL at the time the event occurred. This allows an event handler to identify the appropriate return instruction (ERETU or ERETS).

Specifically, the new RIP value that FRED event delivery establishes is IA32_FRED_CONFIG & ~FFFH for events that occur in ring 3 and (IA32_FRED_CONFIG & ~FFFH) + 256 for events that occur in ring 0.

If the new RIP value is not canonical relative to the current paging mode, FRED event delivery causes a general-protection fault (#GP).[1]

1. If this #GP does not cause a VM exit, FRED event delivery of the #GP will cause a second #GP, which will be converted to a double fault (#DF). If the #DF does not cause a VM exit, FRED event delivery of the #DF will cause a third #GP, resulting in a triple fault, which will either cause a VM exit or take the logical processor to shutdown.

5.1.2 Determining the New Values for Stack Level, RSP, and SSP

FRED transitions support four different stacks for use in ring 0. The CPU identifies the stack currently in use with a 2-bit value called the **current stack level** (CSL).

FRED event delivery first determines the event's stack level and then uses that to determine whether the CSL should change. An event's stack level is based on the CPL, the nature and type of the event, the event's vector (for some event types), and MSRs configured by system software:

- If the event occurred in ring 3, was not a nested exception encountered during event delivery, and was not a double fault (#DF), the event's stack level is 0.
- If the event occurred in ring 0, was a nested exception encountered during event delivery, or was a #DF, the following items apply:
  - If the event is a maskable interrupt, the event's stack level is IA32_FRED_CONFIG[10:9].
  - If the event is an exception or a non-maskable interrupt (NMI), the event's stack level is IA32_FRED_STKLVLS[2*v*+1:2*v*], where *v* is the event's vector (in the range 0–31).[1]
  - The stack level of all other events is 0.

If the event occurred in ring 3, the new stack level is the event's stack level; otherwise, the new stack level is the maximum of the CSL and the event's stack level. (This implies that the CSL is always 0 following FRED event delivery of an event that occurred in ring 3, unless the event was a nested exception or a #DF.)

After determining the new stack level, FRED event delivery identifies the new RSP value as follows:

- If either the CPL or the CSL is changing, the new RSP value will be that of the FRED RSP MSR corresponding to the new stack level.
- Otherwise, the new RSP value will be the current RSP value decremented by IA32_FRED_CONFIG & 1C0H (the multiple of 64 in bits 8:6 of that MSR) and then aligned to a 64-byte boundary (by clearing RSP[5:0]).

If supervisor shadow stacks are enabled, the following items explain how the new SSP value is determined:

- If either the CPL or the CSL is changing, the new SSP value will be that of the FRED SSP MSR corresponding to the new stack level. If the new SSP value is not canonical relative to the current paging mode, or if that value is not 8-byte aligned, FRED event delivery causes a general-protection fault (#GP).

Note: The value of each of IA32_FRED_SSP*i* ($1 \leq i \leq 3$) is always 8-byte aligned, so the alignment check specified above is necessary only if SSP is being loaded from the IA32_PL0_SSP MSR (IA32_FRED_SSP0).

- Otherwise, the new SSP value will be the current SSP value decremented by IA32_FRED_CONFIG & 8 (setting bit 3 of that MSR indicates that SSP should be decremented by 8).

1. Exceptions include the events generated by the INT1, INT3, and INTO instructions, but not those generated by the INT *n* instruction (for any value of *n*).

5.1.3 Establishing the New Context

After determining the details of the new context, FRED event delivery loads registers to establish that context.

For events that occur in ring 3, FRED event delivery updates the CS, SS, and GS segments as well as the IA32_KERNEL_GS_BASE MSR:

- CS:
  - The selector is set to IA32_STAR[47:32] AND FFFCH (this forces CS.RPL to 0).
  - The base address is set to 0. The limit is set to FFFFFH and the G bit is set to 1.
  - The type is set to 11 (execute/read accessed code) and the S bit is set to 1.
  - The DPL is set to 0, the P and L bits are each set to 1, and the D bit is set to 0.
- SS:
  - The selector is set to the new value of the CS selector (above) plus 8 (thus, SS.RPL is also 0).
  - The base address is set to 0. The limit is set to FFFFFH and the G bit is set to 1.
  - The type is set to 3 (read/write accessed data) and the S bit is set to 1.
  - The DPL is set to 0, and the P and B bits are each set to 1.
- GS: FRED event delivery swaps the value of the GS base address and that of the IA32_KERNEL_GS_BASE MSR.

(The above updates occur without any access to the GDT or an LDT.)

For events that occur in ring 0, FRED event delivery does not modify CS, SS, or GS.

After updating the segment registers, FRED event delivery loads RIP, RSP, and CSL with the values determined in Section 5.1.1 and Section 5.1.2. If supervisor shadow stacks are enabled, SSP is loaded with the value determined in Section 5.1.2. RFLAGS is loaded with the value 2 (all bits clear except position 1, which has no function but is always set).

If FRED event delivery incurs a nested exception or VM exit after this point, the processor restores the values that were in these registers before FRED event delivery commenced and only then delivers the nested exception or VM exit.

5.2 Saving Information About the Event and the Old Context

Like IDT event delivery, FRED event delivery saves information about the old context on the stack of the event handler. This information includes the previous context saved in much the same format as that following IDT event delivery, additional information about the event being delivered, and auxiliary information that will guide a subsequent return instruction.

If supervisor shadow stacks are enabled, FRED event delivery also saves information on the event handler's shadow stack.

The memory accesses used to store information on the stacks are performed with supervisor privilege. Any of these memory accesses may result in nested exception. The nested exception (or a double fault to which it may be converted) would then be delivered with FRED event delivery.

5.2.1 Saving Information on the Regular Stack

FRED event delivery saves 64 bytes of information on the new regular stack. The following items provide details:

- The first 8 bytes pushed (bytes 63:56 of the 64-byte stack frame) are not currently defined and will be zero until they are.
- The next 8 bytes pushed (bytes 55:48) contain **event data** and are defined as follows:
  - — If the event being delivered is a page fault (#PF), the event data is the faulting linear address (this is the same value that the #PF loads into CR2).[1]
  - — If the event being delivered is a debug exception (#DB), the event data identifies the nature of the debug exception:
    - Bits 3:0 are B3–B0. When set, each of these bits indicates that the corresponding breakpoint condition was met (and may be set even if its corresponding enabling bit in DR7 is not set).
    - Bits 10:4 are not currently defined and will be zero until they are.
    - Bit 11 is BL. When set, this bit indicates that the cause of the debug exception was acquisition of a bus lock (because IA32_DEBUGCTL[2] = 1).
    - Bit 12 is not currently defined and will be zero until it is.
    - Bit 13 is BD. When set, this bit indicates that the cause of the debug exception was "debug register access detected."
    - Bit 14 is BS. When set, this bit indicates that the cause of the debug exception was the execution of a single instruction (because execution of that instruction commenced with RFLAGS.TF = 1).[2]
    - Bit 15 is not currently defined and will be zero until it is.
    - Bit 16 is RTM. When set, this bit indicates that a debug exception (#DB) or a breakpoint exception (#BP) occurred inside an RTM region while advanced debugging of RTM transactional regions was enabled.
    - Bits 63:17 are not currently defined and will be zero until they are.

    The event data is not exactly the same as that which will be in DR6 following delivery of the #DB. The polarity of bit 11 and bit 16 is inverted in DR6; in addition, delivery of #DB may leave unmodified in DR6 some bits in positions that are clear in the event data and that were already set in DR6.
  - — If the event being delivered is a device-not-available exception (#NM) caused by extended feature disable, the event data indicates the cause of the exception and is the same as that loaded into the IA32_XFD_ERR MSR. If the #NM was not caused by extended feature disable, the event data is zero.
  - — For any other event, the event data is zero.
  - — The event data is determined differently when FRED event delivery is used for an event injected by VM entry. See Section 9.5.4.

1. If the #PF occurred during execution of an instruction in enclave mode (but not during delivery of an event incident to enclave mode), bits 11:0 of the event data are cleared.
2. If in addition IA32_DEBUGCTL.BTF was 1 when the instruction commenced, a debug exception occurs only if the instruction was a taken branch.

- The next 40 bytes pushed (bytes 47:8) are the **return state** and have generally the same format as that used by IDT event delivery. The following items detail the format of the return state on the stack from bottom (highest address) to top:
  - — The stack segment of the interrupted context, 64 bits formatted as follows:
    - Bits 15:0 contain the SS selector.
    - Bits 31:16 are not currently defined and will be zero until they are.
    - Bits 39:32 contain the event's vector. For SYSCALL and SYSENTER (which use FRED event delivery but not IDT event delivery), vectors 1 and 2 are used, respectively.[1]
    - Bits 47:40 are not currently defined and will be zero until they are.
    - Bit 51:48 encode the event type as follows: 0 = external interrupt; 2 = non-maskable interrupt; 3 = hardware exception (e.g., page fault); 4 = software interrupt (INT *n*); 5 = privileged software exception (INT1); 6 = software exception (INT3 or INTO); and 7 = other event (used for SYSCALL and SYSENTER). Other values are not used.
    - Bits 55:52 are not currently defined and will be zero until they are.
    - Bit 56 is set to 1 to indicate that the event was incident to enclave execution. Specifically, it is set in any of the following cases:
      - — The event occurred while the logical processor was in enclave mode.
      - — The event was injected by VM entry (see Section 9.5.4) and the guest interruptibility-state field in the VMCS indicates an "enclave interruption" (bit 4 of the field is 1).
      - — The event was a debug exception that was pending following a VM entry for which guest interruptibility indicates an "enclave interruption" (see above).
      - — The event was a debug exception that was pending following an execution of RSM for which SMRAM indicates an "enclave interruption."
      - — The event was an exception that was encountered during delivery of any of the events above.

      Otherwise, the bit is cleared to 0.
    - Bit 57 is set to 1 if the logical processor had been in 64-bit mode when the event occurred. (A value of 0 indicates an event incident to compatibility mode.)
    - Bit 58 is set to 1 if the event is nested exception encountered during FRED event delivery of another event. This bit is not set if the event is double fault (#DF).
    - Bit 59 is not currently defined and will be zero until it is.
    - Bits 63:60 contain the length of the instruction causing the event if the event type is software interrupt (INT *n*), privileged software exception (INT1), software exception (INT3 or INTO), or other event (when used for SYSCALL or SYSENTER). (The length used is determined differently when FRED event delivery is used for an event of these types injected by VM entry. See Section 9.5.4.) For other event types, these bits are cleared to zero.

1. The event types used by FRED event delivery are the same as those already defined for VMX transitions. For SYSCALL or SYSENTER, FRED event delivery reports event type 7 (other event). For VM entry, that event type is used with vector 0 to indicate a pending MTF VM exit. For that reason, FRED event delivery uses vectors 1 and 2 to indicate SYSCALL and SYSENTER, respectively.

The content of bits 63:32 are referred to as **event information**.

- — RSP of the interrupted context (64 bits).
- — RFLAGS of the interrupted context (64 bits).

  Bit 16 of the RFLAGS field (corresponding to the RF bit) is saved as 1 when delivering events that do the same for IDT event delivery. These are faults (other than instruction breakpoints) as well as any traps or interrupts delivered following partial execution of an instruction (e.g., between iterations of a REP-prefixed string instruction). Delivery of other events save in bit 16 the value that RFLAGS.RF had at the time the event occurred.
- — The code segment of the interrupted context, 64 bits formatted as follows:
  - Bits 15:0 contain the CS selector.
  - Bits 17:16:
    - — For delivery of events that occur in ring 0, these bits report the current stack level (CSL) at the time the event occurred.
    - — For delivery of events that occur in ring 3, these bits are cleared to 0.
  - Bit 24 is set to 1 for FRED event delivery of a hardware exception if interrupt blocking by STI was in effect at the time the exception occurred[1] and is otherwise cleared to 0.
  - Bit 25 is set to 1 for FRED event delivery of SYSCALL, SYSENTER, or INT *n* (for any value of *n*) and is otherwise cleared to 0.
  - Bit 28 is set to 1 if the event being delivered is a non-maskable interrupt (NMI) and is otherwise cleared to 0.
  - Bits 63:29, bits 27:26, and bits 23:18 are not currently defined and will be zero until they are.

  The information saved in bits above the CS selector guides the execution of the FRED return instructions.
- — RIP of the interrupted context (64 bits).

  If the event type is software interrupt (INT *n*), privileged software exception (INT1), software exception (INT3 or INTO), or other event (when used for SYSCALL or SYSENTER); the RIP value saved references the instruction after the one that caused the event being delivered. (If delivery of such an event encounters an exception, the RIP value saved by delivery of the exception will instead reference the instruction that caused the original event.)

- The last 8 bytes pushed (bytes 7:0) contain error code (defined only for certain exceptions; zero if none is defined) in bits 15:0. Bits 63:16 are not currently defined and will be zero until they are.

1. Execution of STI with RFLAGS.IF = 0 blocks interrupts on the instruction boundary following its execution.

5.2.2 Saving Information on the Shadow Stack

If supervisor shadow stacks are enabled and the event being delivered occurred in ring 0, FRED event delivery saves information on the new shadow stack. The following items provide details:

- FRED event delivery writes four bytes of zeroes to the linear address SSP – 4 and then clears SSP[2:0]. This has the following effect:
  - — If the value of SSP had not been 8-byte aligned (it is necessarily 4-byte aligned), 4 bytes of zeroes are stored (as padding) and subsequent shadow-stack pushes will immediately follow those 4 bytes of zeroes.
  - — If the value of SSP had been 8-byte aligned, 4 bytes of zeroes are stored but will be overwritten by subsequent shadow-stack pushes.
- FRED then pushes the old stack level, the old linear instruction pointer, and the old SSP on the shadow stack. Each of these three values is pushed in a separate 8-byte field on the shadow stack.

The write of zeroes and the pushes are all performed as shadow-stack accesses with supervisor privilege.

5.3 Loading Additional State

After saving the old context and other information, FRED event delivery completes operation by loading additional registers and updating other processor state.

If the event occurred in ring 3 and user shadow stacks are enabled, the IA32_PL3_SSP MSR is loaded with the old value of SSP. (The value loaded into the MSR is adjusted so that bits 63:N get the value of bit N–1, where N is the CPU's maximum linear-address width.)

If supervisor indirect branch tracking is enabled, the IA32_S_CET MSR is updated to set the TRACKER value to WAIT_FOR_ENDBRANCH and to clear the SUPPRESS bit to 0. Software should ensure that the instruction referenced by the new RIP value is ENDBR64.

FRED event delivery of a non-maskable interrupt (NMI) blocks NMIs.[1]

A debug trap (single-step trap or data or I/O breakpoint) may be pending at the time another event is delivered. FRED event delivery drops any debug traps that were pending at the time the original event occurred, regardless of the event being delivered. In particular, any pending data or I/O breakpoints (or single-step traps) are no longer pending after INT *n*, INT3, INTO, SYSCALL, or SYSENTER is delivered using FRED event delivery.

Data breakpoints detected during FRED event delivery might not be dropped and may be pending after completion of FRED event delivery. A single-step trap will never be pending following FRED event delivery (even if INT *n*, INT1, INT3, INTO, SYSCALL, or SYSENTER is executed while RFLAGS.TF = 1).

1. For an NMI injected by VM entry, this blocking may apply instead to virtual NMIs. See Section 9.5.4.

6 FRED Return Instructions

FRED defines two new instructions for returning from events delivered by FRED event delivery:

- **ERETS** (Section 6.1) is used to return from events that occur in ring 0; it does not modify CS, SS, or GS. ERETS has the opcode F2 0F 01 CA.
- **ERETU** (Section 6.2) is used to return from events that occur in ring 3; it loads CS and SS based on the stack image and also updates the GS base address. ERETU has the opcode F3 0F 01 CA.

Neither instruction takes explicit operands. These instructions can be executed only if FRED transitions are enabled and only if CPL = 0; in addition, ERETU can be executed only if CSL = 0.

6.1 ERETS (Event Return to Supervisor)

ERETS returns from an event handler while staying in ring 0, establishing the **return context** that was in effect before FRED event delivery. Because it stays within the supervisor context, ERETS does not modify the segment registers CS, SS, or GS. Execution of ERETS causes an invalid-opcode exception (#UD) if FRED transitions are not enabled or if CPL > 0.

ERETS begins by reading and checking the return context from the stack (Section 6.1.1). If supervisor shadow stacks are enabled, it then checks the shadow stack to confirm the validity of this control-flow transfer (Section 6.1.2). Finally, ERETS establishes the return context by loading the appropriate registers (Section 6.1.3).

Appendix A.2 presents the detailed flow of the operation of ERETS.

6.1.1 Loading and Checking the Return Context

ERETS first pops from the regular stack (referenced by RSP) the return context that was saved by FRED event delivery. The context is checked and held by the processor to update register state when the instruction completes. The following items detail the state fields that are popped, from top (lowest address) to bottom (highest address), specifying the checks that are performed:

- The RIP of the return context (64 bits).

  This field must be canonical relative to the current paging mode; otherwise, a #GP occurs.

- The CS selector of the return context (64 bits).

  ERETS does not use bits 15:0 to load CS, but it does ensure that the value of these bits equals that of the current CS selector; otherwise, a #GP occurs.

  Bits 25:24 and bit 28 of this field determine how ERETS manages certain events. See Section 6.1.3.

  ERETS will establish the new stack level as the minimum of the CSL and the value of bits 17:16 of this field.

Bits 23:18, bits 27:26, and bits 63:29 of this field must be zero; otherwise, a #GP occurs.

- The RFLAGS of the return context (64 bits).

  Bit 1 of this field must be 1; bit 3, bit 5, bit 15, bit 17 (VM), and bits 63:22 of the field must be zero; otherwise, a #GP occurs.

- The RSP of the return context (64 bits). This field is not checked.
- The SS selector of the interrupted context (64 bits).

  ERETS does not use bits 15:0 to load SS, but it does ensure that the value of these bits equals that of the current SS selector; otherwise, a #GP occurs.

  Bits 31:16 of this field must be zero; otherwise, a #GP occurs. ERETS ignores bits 63:32 of this field.

6.1.2 Checking the Shadow Stack

If supervisor shadow stacks are enabled, ERETS pops and checks values from the shadow stack (referenced by SSP) that were saved by FRED event delivery. The following items detail the state that is popped from top (lowest address) to bottom (highest address), specifying the checks that are performed:

- The SSP of the return context (64 bits).

  This value must be 4-byte aligned (bits 1:0 must be zero); otherwise, a control protection exception (#CP) occurs.

  This value must be canonical relative to the current paging mode; otherwise, a #GP occurs. (This #GP has priority below the #CP exceptions specified in the following items.)

- The linear instruction pointer of the return context (64 bits).

  This value must equal the RIP of the return context that was popped from the regular stack; otherwise, a #CP occurs.

- The stack level of the return context (low 2 bits of a 64-bit field).

  This value must equal the new stack level as determined in Section 6.1.1 (bits 63:2 of the value must be zero); otherwise, a #CP occurs.

If supervisor shadow stacks are enabled and the new stack level is less than the CSL, ERETS compares the current SSP value and the value of the FRED SSP MSR for the CSL (not the new stack level). (For example, if ERETS is executing with CSL = 2 and is returning to stack level 1, the comparison is with IA32_FRED_SSP2.) If the values are not equal, a #CP occurs.

6.1.3 Establishing the Return Context

After the stack operations described in Section 6.1.1 and Section 6.1.2, ERETS then loads RIP, RFLAGS, RSP, and CSL with the values that were popped earlier from the regular stack. If supervisor shadow stacks are enabled, SSP is loaded with the value that was popped earlier from the shadow stack.

Additional steps are performed based on the value of the popped CS field:

- If bit 24 of the field is 1 and ERETS will result in RFLAGS.IF = 1, blocking by STI is in effect upon completion of ERETS.[1]
- If bit 25 of the field is 1 and ERETS will result in RFLAGS.TF = 1, a single-step trap will be pending upon completion of ERETS.[2]
- If bit 28 of the field (above the selector) is 1, ERETS unblocks NMIs.[3]

6.2 ERETU (Event Return to User)

ERETS returns from an event handler while making a transition to ring 3, establishing the **return context** that was in effect before FRED event delivery. The change of context includes updates to the segment registers CS, SS, or GS. Execution of ERETU causes an invalid-opcode exception (#UD) if FRED transitions are not enabled or if CPL > 0 and a general-protection exception (#GP) if CSL > 0.

ERETU begins by reading and checking the return context from the stack (Section 6.2.1). If supervisor shadow stacks are enabled, it then checks the validity of the old and new shadow-stack pointers (Section 6.2.2). Finally, ERETU establishes the return context by loading the appropriate registers (Section 6.2.3).

Appendix A.3 presents the detailed flow of the operation of ERETU.

6.2.1 Loading and Checking the Return Context

ERETU first pops from the regular stack (referenced by RSP) the return context that was saved by FRED event delivery. The context is checked and held by the processor to update register state when the instruction completes. The following items detail the state fields that are popped, from top (lowest address) to bottom (highest address), specifying the checks that are performed:

- The RIP of the return context (64 bits).

  This field is checked once the new CS configuration is determined (see below).

- The CS selector of the return context (64 bits).

  Bits 15:0 contain the new CS selector itself. ERETU ensures that the value of bits 1:0 is 3; otherwise, a #GP occurs.

  Bit 25 and bit 28 of this field determine how ERETU manages certain events. See Section 6.2.3.

  Bits 24:16, bits 27:26, and bits 63:29 of this field must be zero; otherwise, a #GP occurs.

1. Execution of STI with RFLAGS.IF = 0 blocks interrupts (maskable and nonmaskable) on the instruction boundary following its execution.
2. If ERETS begins execution with RFLAGS.TF = 1, there will always be a single-step debug exception pending after ERETS, regardless of the values on the stack for RFLAGS.TF and CS.
3. If in VMX non-root operation with the 1-setting of the “virtual NMIs” VM-execution control, this step unblocks **virtual** NMIs. See Section 9.

- The RFLAGS of the return context (64 bits).

  Bit 1 of this field must be 1; bit 3, bit 5, bits 13:12 (IOPL), bit 15, bit 17 (VM), and bits 63:22 of the field must be zero; otherwise, a #GP occurs.

Note: Checking IOPL ensures that, when FRED transitions are enabled, IOPL is always 0 when CPL = 3.

- The RSP of the return context (64 bits). This field is not checked.
- The SS selector of the interrupted context (64 bits).

  Bits 15:0 contain the new SS selector itself. ERETU ensures that the value of bits 1:0 is 3; otherwise, a #GP occurs.

  Bits 31:16 of this field must be zero; otherwise, a #GP occurs. ERETU ignores bits 63:32 of this field.

After popping these fields, ERETU determines the configuration of the CS and SS segment registers for the return context according to one of these three cases:

1. If the selector popped for CS is IA32_STAR[63:48] + 16 and the selector popped for SS is IA32_STAR[63:48] + 8, ERETU establishes CS and SS in a standard configuration for ring 3 in 64-bit mode:
   — CS:
     - The selector is set to (IA32_STAR[63:48] + 16) | 3.
     - The base address is set to 0. The limit is set to FFFFFH and the G bit is set to 1.
     - The type is set to 11 (execute/read accessed code) and the S bit is set to 1.
     - The DPL is set to 3, the P and L bits are each set to 1, and the D bit is set to 0.

   — SS:
     - The selector is set to (IA32_STAR[63:48] + 8) | 3.
     - The base address is set to 0. The limit is set to FFFFFH and the G bit is set to 1.
     - The type is set to 3 (read/write accessed data) and the S bit is set to 1.
     - The DPL is set to 3, and the P and B bits are each set to 1.
2. If the selector popped for CS is IA32_STAR[63:48] and the selector popped for SS is IA32_STAR[63:48] + 8, ERETU will establish CS and SS in a standard configuration for ring 3 in compatibility mode:
   — CS:
     - The selector is set to IA32_STAR[63:48] | 3.
     - The base address is set to 0. The limit is set to FFFFFH and the G bit is set to 1.
     - The type is set to 11 (execute/read accessed code) and the S bit is set to 1.
     - The DPL is set to 3, the P bit is set to 1, and the D and L bits are each set to 0.

   — SS:
     - The selector is set to (IA32_STAR[63:48] + 8) | 3.
     - The base address is set to 0. The limit is set to FFFFFH and the G bit is set to 1.
     - The type is set to 3 (read/write accessed data) and the S bit is set to 1.

- The DPL is set to 3, and the P and B bits are each set to 1.

3. Otherwise, the selectors popped for CS and SS are used to load descriptors from the GDT or an LDT as would be done by an execution of IRET. These descriptor loads may cause ERETU to fault as would occur with IRET. In addition, ERETU causes a #GP if the return is to compatibility mode and the RIP of the return context would be beyond the new CS segment limit. If there is no fault, the CS and SS are loaded with the popped values (for the selectors) and with the descriptors read from memory.

If ERETU is returning to 64-bit mode (either case #1 above, or case #3, where the descriptor loaded for CS sets the L bit), a #GP occurs if the RIP of the return context is not canonical relative to the current paging mode.

6.2.2 Checking the Shadow-Stack Pointers

If user shadow stacks are enabled, the SSP of the return context is the value of the IA32_PL3_SSP MSR. If the return is to compatibility mode, a #GP occurs if IA32_PL3_SSP[63:32] are not all zero; if the return is to 64-bit mode, a #GP occurs if the value of IA32_PL3_SSP is not canonical relative to the current paging mode.

If supervisor shadow stacks are enabled, ERETU compares the current SSP value and the value of the IA32_FRED_SSP0 MSR. If the values are not equal, a control protection exception (#CP) occurs.

Note: Execution of ERETU does not access any shadow stack.

6.2.3 Establishing the Return Context

After the stack operations described earlier, ERETU loads RIP, RFLAGS, RSP, CS, and SS with the values identified in Section 6.2.1. All 64 bits of RIP, RFLAGS, and RSP are loaded, even if the return is to compatibility mode. If user shadow stacks are enabled, SSP is loaded with the value for the return context as identified in Section 6.2.2 (from the IA32_PL3_SSP MSR).

ERETU swaps the value of the GS base address and that of the IA32_KERNEL_GS_BASE MSR.

Additional steps are performed based on the value of the popped CS field:

- If bit 25 of the field is 1 and ERETU would result in RFLAGS.TF = 1, a single-step trap will be pending upon completion of ERETU.[1]
- If bit 28 of the field (above the selector) is 1, ERETU unblocks NMIs.[2]

Note: Unlike IRET, ERETU does not make any of DS, ES, FS, or GS null if it is found to have DPL < 3. It is expected that a FRED-enabled operating system will return to ring 3 (in compatibility mode) only when those segments all have DPL = 3.

1. If ERETU began execution with RFLAGS.TF = 1, there will always be a single-step debug exception pending after ERETU, regardless of the values on the stack for RFLAGS.TF and CS.
2. If in VMX non-root operation with the 1-setting of the “virtual NMIs” VM-execution control, this step unblocks **virtual** NMIs. See Section 9.

6.2.4 Interactions Between ERETU and Other Instructions

ERETU provides the same instruction-ordering guarantees as SYSRET. Specifically, instructions following an execution of ERETU may be fetched from memory before earlier instructions complete execution, but they will not execute (even speculatively) until all instructions prior to the ERETU have completed execution. (The later instructions may execute before data stored by the earlier instructions have become globally visible.)

Execution of the UMWAIT instruction will not wait (will not enter an implementation-dependent optimized state) if ERETU was executed before UMWAIT and after the most recent execution of the UMONITOR instruction.

7 FRED and Existing Instructions

The Intel® 64 architecture defines numerous instructions that can effect ring transitions. This section considers those instructions (and others) and describes how enabling FRED transitions affects either their operation or their usage. (Recall that FRED transitions are enabled if CR4.FRED = IA32_EFER.LMA = 1.)

- Section 7.1 identifies instructions that cannot be executed when FRED transitions are enabled.
- Section 7.2 considers far CALL, far JMP, far RET, and IRET. Enabling FRED transitions modifies the operation of these instructions. A FRED-enabled operating system cannot use them for ring transitions or to enter compatibility mode in ring 0.
- Section 7.3 discusses software interrupts and related instructions (INT *n*, INT3, INTO, and INT1). When FRED transitions are enabled, these instructions use FRED event delivery.
- Section 7.4 describes changes to the instructions SYSCALL and SYSENTER. When FRED transitions are enabled, these instructions use FRED event delivery.

7.1 Disallowed Instructions

When FRED transitions are enabled, execution of any of the following instructions causes an invalid-opcode exception (#UD): SWAPGS, SYSEXIT, and SYSRET.

7.2 Far CALL, IRET, Far JMP, and Far RET

Enabling FRED transitions disables the ability of certain existing instructions to effect ring transitions or certain other mode changes.

The far CALL instruction provides a mechanism by which user software can effect a ring transition to more privileged software. The IRET and far RET instructions allow returns to the calling context, and this can cause a ring transition. The operation of these instructions (as well as that of far JMP) is modified when FRED transitions are enabled.

Far CALL can effect a ring transition only if it references a call gate in the GDT or an LDT. (Far JMP can also reference a call gate, but an execution that does so cannot cause a ring transition.) When FRED transitions are enabled, any execution of far CALL or far JMP that references a call gate causes a general-protection exception (#GP). The exception's error code will include the selector that referenced the call gate.

An execution of IRET or far RET causes a ring transition if the RPL value of the target code segment is greater than the CPL. When FRED transitions are enabled, such an execution causes #GP. The exception's error code will include the selector that referenced the code segment.

These restrictions imply that, when they are enabled, FRED transitions are the only ring transitions possible and that it is impossible to enter ring 1 or ring 2.

In addition, enabling FRED transitions disables the ability of software to enter compatibility mode in ring 0. An execution of far CALL, IRET, far JMP, or far RET causes a transition to compatibility mode if it loads CS from a code-segment descriptor in which the L bit is 0. (The L bit is bit 53 of the 64-bit descriptor.) When FRED transitions are enabled, such an execution in ring 0 causes #GP. The exception's error code will include the selector that referenced the code segment.

Note: The restrictions described in this section do not prevent use of far CALL, IRET, far JMP, or far RET to enter compatibility mode when the instruction is executed in ring 3 and (for far CALL and far JMP) does not reference a call gate. They can be used in ring 0 only if their execution stays in ring 0 and in 64-bit mode.

7.3 Software Interrupts and Related Instructions

The Intel 64 architecture supports the following instructions that software in ring 3 can use to invoke the operating system using the IDT:

- INT *n* (opcode CD followed by an immediate byte). There are 256 such software-interrupt instructions, one for each value *n* of the immediate byte (0–255).
- INT3 (opcode CC). This instruction generates a breakpoint exception (#BP) as a trap.
- INTO (opcode CE). If RFLAGS.OF = 1, this instruction generates an overflow exception (#OF) as a trap. If RFLAGS.OF = 0, this instruction does not generate an exception and passes control to the next instruction. Executing INTO in 64-bit mode causes an invalid-opcode exception (#UD), but the instruction can be used to generate #OF in compatibility mode.
- INT1 (opcode F1). This instruction generates a debug exception (#DB) as a trap. Hardware vendors may use INT1 for hardware debug.

When FRED transitions are enabled, an execution of any of these instructions results in FRED event delivery. Section 5.2.1 describes how the resulting FRED event delivery saves event information for these instructions (including the length of the instruction).

Note: IDT event delivery of INT *n*, INT3, and INTO checks the DPL field of the IDT gate and generates a general-protection exception (#GP) if it is less than the CPL. (Delivery of INT1 does not do this.) FRED event delivery does not use the IDT and thus does not perform this check. The event handlers of a FRED-enabled operating system should check the event type and vector to identify situations that would have resulted in a fault with IDT event delivery.

7.4 SYSCALL and SYSENTER

The Intel 64 architecture supports two instructions that software in ring 3 can use to invoke the operating system without using the IDT: SYSCALL and SYSENTER.

When FRED transitions are enabled, the operation of SYSCALL is modified to use FRED event delivery (Section 5) in place of its existing operation.

The following pseudocode describes the operation of SYSCALL on a CPU that supports FRED transitions, detailing the order of certain fault checking:

```
IF IA32_EFER.LMA = 0                         // SYSCALL can be used only by a 64-bit operating system
    THEN #UD;
ELSIF CR4.FRED = 0
    THEN
        IF IA32_EFER.SCE = 0 OR CS.L = 0
            THEN #UD;
            ELSE existing SYSCALL operation;
        FI;
    ELSE    // FRED does not require enabling in IA32_EFER
            // SYSCALL is allowed in compatibility mode
        FRED event delivery of SYSCALL;    // the instruction's length will be saved on the stack
FI;
```

A FRED-enabled operating system should use ERETU (Section 6.2) instead of SYSRET to return after handling a system call invoked by an execution of SYSCALL in ring 3. (Recall that any execution of SYSRET causes #UD when FRED transitions are enabled.) A FRED-enabled operating system will normally use ERETU to return from any event that occurred when in ring 3.

(Because the SYSRET instruction always returns to ring 3, use of SYSCALL has previously been effectively limited to ring 3. When SYSCALL uses FRED event delivery, that instruction can be used effectively in ring 0. If this is done, a FRED-enabled operating system would naturally return with ERETS, remaining in ring 0.)

The operation of SYSENTER is also modified to use FRED event delivery when FRED transitions are enabled. The following pseudocode describes the operation of SYSENTER on a CPU that supports FRED transitions, detailing the order of certain fault checking:

```
IF CR0.PE = 0 OR ((IA32_EFER.LMA = 0 OR CR4.FRED = 0) AND IA32_SYSENTER_CS[15:2] = 0)
    THEN #GP;        // IA32_SYSENTER_CS applies only if FRED transitions are not enabled
ELSIF IA32_EFER.LMA = 0 OR CR4.FRED = 0
    THEN existing SYSENTER operation;
    ELSE FRED event delivery of SYSENTER;    // the instruction's length will be saved on the stack
FI;
```

A FRED-enabled operating system should use ERETU (Section 6.2) instead of SYSEXIT to return after handling a system call invoked by an execution of SYSENTER in ring 3. (Recall that any execution of SYSEXIT causes #UD when FRED transitions are enabled.)

8 LKGS: Support for Managing GS

64-bit operating systems and their applications use the GS segment for thread-local storage (TLS). Because the operating system and applications use the TLS at different addresses, they use different base addresses for that segment.

FRED transitions ensure that an operating system can always operate with its own GS base address:

- For events that occur in ring 3, FRED event delivery swaps the GS base address with the IA32_KERNEL_GS_BASE MSR.
- ERETU (the FRED transition that returns to ring 3) also swaps the GS base address with the IA32_KERNEL_GS_BASE MSR.

An operating system can modify the GS base address of a user thread (e.g., as part of a context switch) by updating the IA32_KERNEL_GS_BASE MSR. However, existing instructions do not allow an operating system to modify other attributes of the GS segment without compromising its ability always to operate with its own GS base address. This is because the instructions that update those attributes (by loading them from a descriptor table) also update the GS base address.

The FRED architecture addresses this deficiency with a new instruction **LKGS** (abbreviating "load into IA32_KERNEL_GS_BASE"). LKGS behaves like the MOV to GS instruction except that it loads the base address into the IA32_KERNEL_GS_BASE MSR instead of the GS segment's descriptor cache.

The following items provide details regarding the LKGS instruction:

- Support for LKGS is enumerated with the feature flag CPUID.(EAX=7,ECX=1):EAX.LKGS[bit 18].
- LKGS has the opcode F2 0F 00 /6.
- Execution of LKGS causes an invalid-opcode exception (#UD) if CPL > 0 or if the logical processor is not in 64-bit mode.
- LKGS takes a single 16-bit operand and uses it to load a descriptor from the GDT or an LDT. It is subject to the same faults as would be incurred by the MOV to GS instruction. If there is no fault, the operand is loaded into the GS selector.
- The descriptor read by LKGS is loaded into the GS segment's descriptor cache as is done by the MOV to GS instruction except that the base address in the descriptor is not loaded into the descriptor cache (the base address in the cache is unmodified) but is instead loaded into the IA32_KERNEL_GS_BASE MSR. Because the base address in the descriptor is only 32 bits, LKGS clears the upper 32 bits of the 64-bit IA32_KERNEL_GS_BASE MSR.
- If the 16-bit operand is a null selector (values 0–3), the GS segment is marked unusable outside 64-bit mode and zero is loaded into the IA32_KERNEL_GS_BASE MSR. (The base address in the GS descriptor cache is not modified.)

The LKGS instruction and the nature of FRED transitions (above) remove any need for an operating system to use the SWAPGS instruction. As noted in Section 7.1, an execution of SWAPGS causes an invalid-opcode exception (#UD) if FRED transitions are enabled.

9 VMX Interactions with FRED Transitions

This section describes interactions between FRED transitions and the VMX architecture.

Section 9.1 explains the renaming of certain existing fields in the VMCS. Section 9.2 introduces a new VMX feature necessary for proper virtualization of FRED event delivery. Section 9.3 details additions to the VMCS to support FRED transitions. Section 9.4 describes the operation of FRED transitions in VMX non-root operation. Section 9.5 and Section 9.6 discuss interactions with VM entries and VM exits, respectively.

9.1 Renaming of Existing VMCS Fields

The VMCS contains certain fields related to event delivery. These fields are being renamed for clarity and consistency with FRED event delivery. The following items provide details:

- For events causing VM exits:
  - Basic event identification (VMCS encoding 4404H):
    - Old name: VM-exit interruption information
    - New name: **Exiting-event identification**
  - Error code (VMCS encoding 4406H):
    - Old name: VM-exit interruption error code
    - New name: **Exiting-event error code**
- For VM exits occurring during event delivery:
  - Basic event identification (VMCS encoding 4408H):
    - Old name: IDT-vectoring information
    - New name: **Original-event identification**
  - Error code (VMCS encoding 440AH):
    - Old name: IDT-vectoring error code
    - New name: **Original-event error code**
- For events injected by VM entry:
  - Basic event identification (VMCS encoding 4016H):
    - Old name: VM-entry interruption information
    - New name: **Injected-event identification**
  - Error code (VMCS encoding 4018H):
    - Old name: VM-entry exception error code
    - New name: **Injected-event error code**

For the three basic event identification fields, the sub-field at bits 10:8 are being renamed from “interruption type” to “**event type**.”

9.2 New VMX Feature: VMX Nested-Exception Support

As noted in Section 5.1.2, the event stack level used by FRED event delivery depends on whether the event was a nested exception encountered during delivery of another event. In addition, FRED event delivery sets a bit on the stack when delivering a nested exception. For proper virtualization of these details, processors that support FRED will also support a new VMX feature called **VMX nested-exception support**. A processor enumerates VMX nested-exception support by setting bit 58 in the VMX capability MSR IA32_VMX_BASIC (index 480H). Any processor that enumerates support for FRED transitions (see Section 4.1) will also enumerate VMX nested-exception support.

VMX nested-exception support changes the way in which VM exits establish certain VM-exit information fields and the way in which VM entries use a related VM-entry control field:

- Exiting-event identification. This VM-exit information field is valid for VM exits due to events that would have been delivered to guest software (with IDT event delivery or FRED event delivery) if they had not caused a VM exit. The field provides details about the nature of the event causing the VM exit.

  VMX nested-exception support defines bit 13 of this field, which is always saved as 0 by processors without VMX nested-exception support.

  With VMX nested-exception support, a VM exit saves bit 13 of this field as 1 if the VM exit is due to a nested exception encountered during delivery of an earlier event (but not for VM exits due to #DF). This is done even if FRED transitions are not enabled (i.e., even if that earlier event was being delivered using IDT event delivery).

  Other VM exits for which the field is valid (including VM exit due to #DF) save bit 13 as 0.

  (The value of this bit is always identical to that of the valid bit of the original-event identification field.)

- Original-event identification. This VM-exit information field is valid for VM exits due to events encountered during delivery of an earlier event being delivered to guest software with IDT event delivery or FRED event delivery (including SYSCALL and SYSENTER with FRED event delivery). The field provides details about the nature of that earlier event.

  VMX nested-exception support defines bit 13 of this field, which is always saved as 0 by processors without VMX nested-exception support.

  With VMX nested-exception support, a VM exit saves bit 13 of this field as 1 if the earlier event was itself a nested exception encountered during delivery of another event (but not for VM exits encountered during delivery of #DF). This feature applies even if FRED is not enabled (i.e., even if that first event was being delivered using IDT event delivery).

  Other VM exits for which the field is valid (including VM exits due to events encountered during delivery of #DF) save bit 13 as 0.

- Injected-event identification. Software establishes a valid value in this VM-entry control field to specify an event to be injected at the end of the next VM entry.

  VMX nested-exception support defines bit 13 of this field. (For processors without VMX nested-exception support, VM entry fails if this bit is 1.)

  With VMX nested-exception support, VM entry allows bit 13 to be 1 if the field indicates injection of a hardware exception (bits 10:8, the type, should have value

3). If FRED transitions will be enabled in the guest and thus the injected exception will be delivered using FRED event delivery, the event information saved on the stack will set a bit to indicate that the event was a nested exception (see Section 5.2.1). In addition, the event's stack level is determined as if the event had been a nested exception encountered during delivery of another event (see Section 5.1.2). If FRED transitions will not be enabled in the guest, bit 13 of the field is ignored.

VM entry fails if bit 13 of this field is 1 and the field indicates injection of an event other than an exception (bits 10:8 of the field have value other than 3).

9.3 VMCS Changes for FRED Transitions

A VMM (or its hosting operating system) should be able to use FRED transitions and to allow guest software to do so. For that reason, VMX transitions (VM entries and VM exits) must establish context sufficient to support FRED event delivery immediately after the transition. In addition, VM exits should be able to save the corresponding guest context before loading that for the VMM.

To support this context management, new fields are added to the VMCS that correspond to some of the following configuration MSRs identified in Section 4.3:

- Nine (9) MSRs added for FRED transitions: IA32_FRED_CONFIG, IA32_FRED_RSP0, IA32_FRED_RSP1, IA32_FRED_RSP2, IA32_FRED_RSP3, IA32_FRED_STKLVLS, IA32_FRED_SSP1, IA32_FRED_SSP2, and IA32_FRED_SSP3.
- Three (3) existing MSRs used by FRED transitions: IA32_STAR, IA32_KERNEL_GS_BASE, and IA32_PL0_SSP (also known as IA32_FRED_SSP0).

Fields for some of these MSRs are added to both the host-state and guest-state areas of the VMCS. Details are provided in Section 9.3.1 and Section 9.3.2. Section 9.3.3 enumerates the new VMX controls that manage the new MSRs.

As will be explained, VMCS fields are not needed for all of these MSRs. In particular, fields are not added for the following MSRs: IA32_FRED_RSP0, IA32_STAR, IA32_KERNEL_GS_BASE, and IA32_PL0_SSP. Before VM entry, a virtual-machine monitor should ensure that these MSRs contain the values expected by guest software in the virtual machine being entered (e.g., with the WRMSR instruction).

As explained in Section 5.2.1, FRED event delivery saves **event data** that provide additional information about certain events (e.g., page faults). To support proper handling of event data across VMX transitions two new fields are added to the VMCS. These are described in Section 9.3.4.

9.3.1 Host-State Area

As noted earlier, each VM exit must establish the configuration required for FRED transitions that might occur immediately after the VM exit.

The CPL is always 0 after any VM exit. For that reason, delivery of an event that arrives immediately after a VM exit cannot cause a ring transition; the return from such an event will use ERETS, not ERETU. As a result, the following MSRs will not be needed for delivery of and return from such an event:

- IA32_FRED_RSP0 and IA32_PL0_SSP (also known as IA32_FRED_SSP0). If CPL = 0, FRED event delivery loads RSP from a FRED RSP MSR only if the stack level is numerically increasing; consequently, such FRED event delivery would not use

IA32_FRED_RSP0 or IA32_PL0_SSP. Similarly, ERETS checks IA32_FRED_SSP*i* only when returning from stack level *i* to a numerically lower stack level; as a result, ERETS would never refer to IA32_PL0_SSP. (ERETS does not use the FRED RSP MSRs at all.)

- IA32_STAR. FRED event delivery uses this MSR only when loading CS and SS when delivering an event that arrives in ring 3. ERETS does not use this MSR.
- IA32_KERNEL_GS_BASE. FRED event delivery swaps this MSR with the GS base address only when delivering an event that arrives in ring 3. ERETS does not do this swapping.

Thus, 64-bit fields are added to host-state area of the VMCS for the following MSRs (the encoding pair for each field is shown parenthetically):

- IA32_FRED_CONFIG (2C08H/2C09H)
- IA32_FRED_RSP1 (2C0AH/2C0BH)
- IA32_FRED_RSP2 (2C0CH/2C0DH)
- IA32_FRED_RSP3 (2C0EH/2C0FH)
- IA32_FRED_STKLVLS (2C10H/2C11H)
- IA32_FRED_SSP1 (2C12H/2C13H)
- IA32_FRED_SSP2 (2C14H/2C15H)
- IA32_FRED_SSP3 (2C16H/2C17H)

9.3.2 Guest-State Area

Section 9.3.1 identified fields for nine MSRs added to the host-state area of the VMCS. Since these MSRs will be loaded by VM exits, it must be possible for their guest values to be saved earlier by those VM exits. For that reason, nine corresponding 64-bit fields are added to the guest-state area of the VMCS (the encoding pair for each field is shown parenthetically):

- IA32_FRED_CONFIG (281AH/281BH)
- IA32_FRED_RSP1 (281CH/281DH)
- IA32_FRED_RSP2 (281EH/281FH)
- IA32_FRED_RSP3 (2820H/2821H)
- IA32_FRED_STKLVLS (2822H/2823H)
- IA32_FRED_SSP1 (2824H/2825H)
- IA32_FRED_SSP2 (2826H/2827H)
- IA32_FRED_SSP3 (2828H/2829H)

9.3.3 VMX Controls

The following VMX controls are added to support management of FRED context:

- VM-entry control 23 is "load FRED." If this control is set, VM entries load the guest FRED state identified in Section 9.3.2.
- Secondary VM-exit control 0 is "save FRED." If this control is set, VM exits save the guest FRED state identified in Section 9.3.2.

- Secondary VM-exit control 1 is "load FRED." If this control is set, VM exits load the host FRED state identified in Section 9.3.1.

9.3.4 Event-Data Fields

Two new VMCS fields are defined for the event data saved by FRED event delivery

The first new field is a 64-bit VMX control field called **injected-event data**. If VM-entry injection of an event uses FRED event delivery, the event data saved on the stack is the value of this field (see Section 9.5.4). This field has uses the encoding pair 2052H/2053H.

The second new field is a 64-bit exit-information field called **original-event data**. If a VM exit occurs during FRED event delivery, the event data that would have saved on the stack is instead stored into this field (see Section 9.6.3). This field uses the encoding pair 2404H/2405H.

Note: No new exit-information field is added for exiting-event data (event data for event causing a VM exit). As explained in Section 9.6.2, such data may be saved in the existing exit-qualification field.

9.4 FRED Transitions and VMX Non-Root Operation

If FRED transitions are enabled in VMX non-root operation, the architectural changes identified in this specification apply to guest execution. Interactions between the features are described in this section.

9.4.1 VM Exits Due to Events

A VMM may use existing VMX features to specify that VM exits should occur on the occurrence of events that would be delivered with FRED event delivery. These events include external interrupts, non-maskable interrupts (NMIs), and exceptions (including those generated by INT1, INT3, and INTO). If such an event occurs, any specified VM exit occurs regardless of whether FRED transitions are enabled. FRED event delivery does not occur. See Section 9.6 for more details.

9.4.2 NMI Blocking

As specified in Section 5.3, FRED event delivery of a non-maskable interrupt (NMI) blocks NMIs. That does not change in VMX non-root operation. Note, however, that an NMI can be delivered in VMX non-root operation only if the "NMI exiting" VM-execution control is 0.

As specified in Section 6.1.3 and Section 6.2.3, ERETS and ERETU each unblocks NMIs if bit 16 of the popped CS field is 1. The following items detail how this behavior may be changed in VMX non-root operation, depending on the settings of certain VM-execution controls:

- If the "NMI exiting" VM-execution control is 0, this behavior of ERETS and ERETU is not modified (they unblock NMIs as indicated above).
- If the "NMI exiting" VM-execution control is 1, ERETS and ERETU do not unblock physical NMIs.
- If the "virtual NMIs" VM-execution control is 1 (which implies that the "NMI exiting" VM-execution control is also 1), the logical processor tracks virtual-NMI blocking. In

this case, ERETS and ERETU each unblocks virtual NMIs if bit 16 of the popped CS field is 1.

(If the "NMI exiting" VM-execution control is 1 and the "virtual NMIs" VM-execution control is 0, ERETS and ERETU ignore bit 16 of the popped CS field.)

9.5 FRED Transitions and VM Entries

This section describes the interactions between VM entries and various aspects of FRED transitions.

Some aspects of VM entry are changed if FRED transitions will be enabled following VM entry. FRED transitions are enabled following VM entry if both of the following hold:

- The "IA-32e mode guest" VM-entry control is 1.
- Bit 32 (FRED) of the CR4 field in the guest-state area is 1.

9.5.1 Checks on VMX Controls

VM entry performs checks on the various VMX controls, including those related to event injection.

If FRED transitions would be enabled following VM entry (see above), the following relaxations apply to the checks that are performed on the injected-event identification field when the valid bit (bit 31) in that field is set:

- If the field's "event type" (bits 10:8) is 7 (other event), the field's vector (bits 7:0) may have value 1 (indicating SYSCALL) or value 2 (indicating SYSENTER).[1] If it does, the value of the VM-entry instruction-length field must be in the range 0–15.
- There are no checks on the field's "deliver error code" bit (bit 11).

Regardless of whether FRED transitions would be enabled following VM entry, processors with VMX nested-exception support (Section 9.2) apply the following relaxation to checks on the injected-event field when the valid bit (bit 31) in that field is set: if the field's "event type" (bits 10:8) is 3 (hardware exception), bit 13 of the field may have value 1 (indicating a nested exception).

9.5.2 State Checking by VM Entries

Support for FRED transitions impacts VM-entry state checking in three ways:

- The ways in which host FRED state is checked (Section 9.5.2.1).
- The ways in which guest FRED state is checked (Section 9.5.2.2).
- New checks on existing guest state if FRED transitions would be enabled after VM entry (Section 9.5.2.3).

1. Prior to the introduction of FRED transitions, the vector value had to be zero, indicating "pending MTF VM exit."

9.5.2.1 State Checking of Host FRED State

If the “load FRED” VM-exit control is 1, VM entries check the host FRED state in the VMCS that was identified in Section 9.3.1. If the field for any MSR contains a value that is not valid for that MSR (see Section 4.3), VM entry fails as is normally the case when checking host state. The following items provide specifics of the properties that must hold:

- IA32_FRED_CONFIG: Bit 2, bits 5:4, and bit 11 of the field must be zero. The upper bits of the field must be such that the field’s value is canonical relative to the processor’s maximum linear-address width.
- IA32_FRED_RSP1–IA32_FRED_RSP3: The value of each of these fields must be canonical relative to the processor’s maximum linear-address width, and bits 5:0 of each field must be zero.
- IA32_FRED_SSP1–IA32_FRED_SSP3: The value of each of these fields must be canonical relative to the processor’s maximum linear-address width, and bits 2:0 of each field must be zero.

9.5.2.2 State Checking of Guest FRED State

If the “load FRED” VM-entry control is 1, VM entries check the guest FRED state in the VMCS that was identified in Section 9.3.2. If the field for any MSR contains a value that is not valid for that MSR, VM entry fails as is normally the case when checking guest state. The following items provide specifics of the properties that must hold:

- IA32_FRED_CONFIG: Bit 2, bits 5:4, and bit 11 of the field must be zero. The upper bits of the field must be such that its value is canonical relative to the processor’s maximum linear-address width.
- IA32_FRED_RSP1–IA32_FRED_RSP3: The value of each of these fields must be canonical relative to the processor’s maximum linear-address width, and bits 5:0 of each field must be zero.
- IA32_FRED_SSP1–IA32_FRED_SSP3: The value of each of these fields must be canonical relative to the processor’s maximum linear-address width, and bits 2:0 of each field must be zero.

9.5.2.3 State Checking If FRED Transitions Would Be Enabled After VM Entry

As noted elsewhere, execution is constrained when FRED transitions are enabled: software cannot enter ring 1 or ring 2, nor can it enter ring 0 in compatibility mode; in addition, IOPL must be 0 when CPL is 3. Checks are added to VM entry to enforce these limitations.

If FRED transitions would be enabled following VM entry (see above), VM entry performs the following checks on guest state in the VMCS:

- The DPL value (bits 6:5) in the SS attributes field must be 0 or 3.[1]
- If the DPL value in the SS attributes field is 0, the L bit (bit 13) in the CS attributes field must be 1.
- If the DPL value in the SS attributes field is 3, the IOPL value (bits 13:12) in the RFLAGS field must be 0.

1. SS.DPL corresponds to the logical processor’s current privilege level (CPL).

If any of these checks fail, VM entry fails as is normally the case when checking guest state.

9.5.3 State Loading by VM Entries

If the "load FRED" VM-entry control is 1, VM entries load the guest FRED state identified in Section 9.3.2 from the VMCS.

9.5.4 VM-Entry Event Injection

If the valid bit (bit 31) of the injected-event identification field is 1, VM entry injects an event.

For IDT event delivery, VM entry can be used to inject an external interrupt, non-maskable interrupt (NMI), exception (including those caused by INT1, INT3, and INTO), or software interrupt. If FRED transitions will be enabled after the VM entry (see above), injection of any of these events uses FRED event delivery (instead of IDT event delivery).

In addition, as noted in Section 9.5.1, VM entry can inject an event for SYSCALL or SYSENTER if FRED transitions will be enabled after the VM entry.

If bit 13 of the injected-event identification field is 1 (implying that the event is an exception; see Section 9.5.1) and the injected event is delivered using FRED event delivery, the event's stack level is determined as if the event had been encountered during delivery of another event (see Section 5.1.2).

Section 5.2.1 specifies the event data that FRED event delivery of certain events saves on the stack. When FRED event delivery is used for an event injected by VM entry, the event data saved is the value of the injected-event-data field in the VMCS. This value is used instead of what is specified in Section 5.2.1 and is done for all injected events using FRED event delivery.

Section 5.2.1 specifies that FRED event delivery of exceptions saves as part of event information a bit indicating whether the exception had been encountered during delivery of another event. When FRED event delivery is used for such an event injected by VM entry, the bit saved is the value of bit 13 of the injected-event identification field.

Section 5.2.1 specifies an instruction length that FRED event delivery of certain events saves as part of event information. When FRED event delivery is used for such an event injected by VM entry, the instruction length saved is the value of the VM-entry instruction-length field in the VMCS.

The following items describe the existing treatment of RIP by VM-entry event injection:

1. If VM entry successfully injects (with no nested exception) an event with type external interrupt, NMI, or hardware exception, the guest RIP (as loaded from the VMCS) is pushed on the stack.
2. If VM entry successfully injects (with no nested exception) an event with type software interrupt, privileged software exception, or software exception, the guest RIP is incremented by the VM-entry instruction length before being pushed on the stack.

3. If VM entry encounters an exception while injecting an event and that exception does not cause a VM exit, the guest RIP is pushed on the stack regardless of event type or VM-entry instruction length.
4. If VM entry encounters a VM exit while injecting an event (perhaps due to an exception), the RIP value saved by the VM exit is the guest RIP loaded from the VMCS. If the injected event had type software interrupt, privileged software exception, or software exception, the value saved for the VM-exit instruction length is the VM-entry instruction length.

Item #2 of this existing treatment will apply also if VM entry is injecting SYSCALL or SYSENTER using FRED event delivery. For item #4, the treatment of the instruction length is extended to apply also to the injection of SYSCALL and SYSENTER.

If VM entry is injecting an NMI, physical-NMI blocking is not changed, but virtual NMIs are blocked if the "virtual NMIs" VM-execution control is 1.

The following items provide details of how FRED event delivery of an event injected by VM entry sets bits in the CS-selector field saved on the stack (see Section 5.2.1):

- Bits 17:16 are set to the value of bits 1:0 of the IA32_FRED_CONFIG field in the guest-state area of the VMCS (those bits indicate the CSL).
- Bit 24 is set to the value of bit 0 of the interruptibility-state field in the guest-state area of the VMCS (that bit indicates blocking by STI). (There will be no blocking by STI after FRED event delivery.)
- Bit 25 is set if and only if the value of bits 10:8 in the VM-entry interruption information field in the VMCS is 4 (indicating event type software interrupt) or 7 (indicating event type "other event," used for SYSCALL and SYSENTER).[1]
- Bit 28 is set if and only if the value of bits 10:8 in the VM-entry interruption information field in the VMCS is 2 (indicating event type NMI).

9.6 FRED Transitions and VM Exits

This section describes the interactions between VM exits and various aspects of FRED transitions.

9.6.1 State Management by VM Exits

If the "save FRED" VM-exit control is 1, VM exits save the guest FRED state identified in Section 9.3.2 into the VMCS.

If the "load FRED" VM-exit control is 1, VM exits load the host FRED state identified in Section 9.3.1 from the VMCS.

9.6.2 VM Exits Caused by Events That Would be Delivered by FRED

If an event that would use FRED event delivery instead causes VM exit, information about the event is saved into the exiting-event identification and error-code fields of the VMCS as would be done if FRED transitions were not enabled, with the following exceptions:

1. Event type 7 may also be used for MTF VM exits, but these are not delivered using FRED event delivery.

- Bit 11 of the exiting-event identification field indicates whether the error code field is valid. For VM exits due to events that occur while FRED transitions are enabled, this bit is always saved as 1.
- Bit 13 of the exiting-event identification field is set if the VM exit is due to a nested exception encountered during delivery of an earlier event. Other VM exits (including VM exit due to #DF) clear the bit.
- For events that occur while FRED transitions are enabled, the exiting-event error code is always defined. (It receives whatever value the event would have saved for an error code as determined by Section 5.2.1; this value is zero when an error code was not already defined.)

For some events for which event data is defined (see Section 5.2.1), the event data is saved in the exit-qualification field. (This is done for #DB and #PF.)

Note: VM exits due to #NM do not save the event data into the VMCS. Any event data is recorded in the IA32_XFD_ERR MSR.

9.6.3 VM Exits During FRED Event Delivery

A VM exit may occur during FRED event delivery, due either to a nested exception (configured to cause a VM exit) or to some VMX-specific occurrence (e.g., an EPT violation).

The VMX architecture treats such a case in the same way that it would treat a VM exit incident to IDT event delivery. Specifically, no processor state is updated by the FRED event delivery that encountered the VM exit. (The VM exit may occur after there have been writes to memory, e.g., to push data on the stack.)

In these cases, information about the event is saved into the original-event identification and error-code fields of the VMCS as would be done if FRED transitions were not enabled, with the following exceptions:

- Bit 11 of the original-event identification field indicates whether the error code field is valid. For VM exits that occur during FRED event delivery, this bit is always saved as 1.
- Bit 13 of the original-event identification field is set if the original event was a nested exception encountered during delivery of another event. Other VM exits (including VM exit due to events encountered during delivery of #DF) clear the bit.
- For VM exits that occur during FRED event delivery, the original-event error code is always defined. (It receives whatever value the event would have saved for an error code as determined by Section 5.2.1; this value is zero when an error code was not already defined.)

In addition, the event data that FRED event delivery would save on the stack (see Section 5.2.1) is saved into the original-event-data field in the VMCS. This is done for all events (if FRED event delivery would have saved zero for event data, that value is saved into the VMCS).[1]

The existing treatment of VM exits encountered during IDT event delivery of events with type software interrupt (INT *n*), privileged software exception (INT1), or software exception (INT3 or INTO) is that the length of the instruction is saved into the VM-exit instruction-length field in the VMCS. This treatment will apply also to FRED event

1. The value of the original-event-data field is undefined following all other VM exits, including those that occur during IDT event delivery.

delivery, including FRED event delivery of SYSCALL or SYSENTER. (See Section 9.5.4 for the case in which the FRED event delivery resulted from VM-entry event injection.)

In general, for VMX features that have special treatment during IDT event delivery (e.g., conversion of EPT violations to virtualization exceptions), that special treatment applies as well to FRED event delivery.

9.6.4 VM Exits During FRED Return Instructions

A VM exit may occur during execution of ERETS or ERETU due either to an exception (if configured to cause a VM exit) or to some VMX-specific occurrence (e.g., an EPT violation).

The VMX architecture treats this case in the same way that it generally treats VM exits incident to other instructions: for fault-like VM exits, no register state is updated.

In particular, an execution of ERETS and ERETU that causes a VM exit does not unblock NMIs (or virtual NMIs). Because of this, such a VM exit that results from a fault, EPT violation, page-modification log-full event, SPPT misconfiguration, or SPPT miss encountered by ERETS or ERETU never sets bit 12 of the exit qualification. (The processor sets this bit only for VM exits encountered by an execution of IRET that unblocks NMIs.)

10 Changes to SMIs and RSM

Delivery of a system-management interrupt (SMI) saves the processor's pre-SMI context to a specific region within system-management RAM (SMRAM).

The SMRAM state-save region allocates 64 bits for CR4 at offset 7E40H. Prior to the introduction of FRED transitions, CR4[63:32] was not used, and SMI delivery saved only CR4[31:0]. On processors that support FRED transitions (which are enabled in CR4[32]; see Section 4.2), SMI delivery saves all 64 bits of CR4.

The RSM instruction (Resume from System Management Mode), which can be executed only in system-management mode (SMM), effects a return from SMM by restoring register state that was saved by delivery of the most recent SMI.

Prior to the introduction of FRED transitions, RSM read from SMRAM only the value of CR4[31:0] and did not restore CR4[63:32]. On processors that support FRED transitions, RSM restores all 64 bits of CR4.

If execution of RSM detects that it would restore invalid state, the logical processor enters the shutdown state and generates a special bus cycle to indicate this fact.

On processors that support FRED transitions, execution of RSM leads to shutdown in the following situations (in addition to those already defined):

- If FRED transitions would be enabled after RSM (CR4.FRED = IA32_EFER.LMA = 1) and CPL would be 1 or 2.
- If FRED transitions would be enabled after RSM, CPL would be 0, and the logical processor would be in compatibility mode.
- If FRED transitions would be enabled after RSM, CPL would be 3, and IOPL would be non-zero.

A Detailed Pseudocode

The appendix gives detailed pseudocode for FRED event delivery (Appendix A.1), ERETS (Appendix A.2), and ERETU (Appendix A.3). Unless otherwise noted, the pseudocode in this appendix should be considered definitive for the FRED transitions. (This appendix does not provide all details of interactions with the VMX architecture.)

A.1 Detailed Operation of FRED Event Delivery

The appendix presents detailed pseudocode for the operation of FRED event delivery.

It does not include details of how event information is formatted or how event data is determined. These details are in Section 5.2.1.

```
// HOLD OLD STATE IN TEMPORARIES
oldRIP := RIP;
oldCS := CS;                         // oldCS is 8 bytes; the upper 6 bytes are defined below
oldCPL := CPL;                       // the same as oldCS[1:0]
oldRFLAGS := RFLAGS;
oldSS := SS;                         // oldSS is 8 bytes; upper 6 bytes are zero
oldRSP := RSP;
IF CPL = 3
    THEN oldCSL := 0;
    ELSE oldCSL := CSL;
FI;
oldGSB := GS.base;
oldSSP := SSP;                       // used only when shadow stacks are enabled
// ERETS and ERETU will restore the oldRFLAGS to RFLAGS
// Before saving, event delivery updates oldRFLAGS to set RF when appropriate
IF the event being delivered is a fault other than an instruction breakpoint OR
    the event being delivered is a trap or interrupt following partial execution of an instruction
    (e.g., between iterations of a REP-prefixed string instruction)
    THEN oldRFLAGS[16] := 1;
FI;
// Update bits above CS selector to hold additional information
// ERETS and ERETU will use these
oldCS[17:16] := oldCSL;
IF STI blocking was in effect when the event occurred
    THEN oldCS[24] := 1;

    THEN SSP := newSSP;
FI;

// SAVE STATE ON STACKS
// Save return state on new regular stack; memory accesses here have supervisor privilege
push8B 00000000_00000000H;              // First 8 bytes pushed are all zero
push8B event data as defined in Section 5.2.1;
push8B oldSS;
push8B oldRSP;
push8B oldRFLAGS;
push8B oldCS;
push8B oldRIP;
push8B errorcode;
```

```
// If supervisor shadow stacks enabled and old CPL was 0, save data on new shadow stack
IF CR4.CET = 1 AND IA32_S_CET.SH_STK_EN = 1 AND oldCPL = 0
    THEN
        store 4 bytes of zeroes to address SSP – 4;// shadow-stack access
        SSP := SSP & ~7;                    // aligns SSP to 8B boundary
        pushSS_8B oldCSL;                   // low 2 bits of 64-bit field
        pushSS_8B oldRIP;
        pushSS_8B oldSSP;
FI;

// UPDATE ADDITIONAL STATE
// update additional CET state as needed (SSP was updated earlier)
IF CR4.CET = 1
    THEN
        IF oldCPL = 3 AND IA32_U_CET.SH_STK_EN = 1
            THEN    // adjust so bits 63:N get the value of bit N–1
                    // N = CPU's maximum linear-address width
                IA32_PL3_SSP := LA_adjust(oldSSP);
        FI;
        IF IA32_S_CET.ENDBR_EN = 1
            THEN IA32_S_CET[11:10] := 10b;          // WAIT_FOR_ENDBRANCH with SUPPRESS = 0
        FI;
FI;
// update event-related state
clear any debug traps that were pending prior to FRED event delivery;
IF event being delivered is an NMI
    THEN block NMIs;[1]
FI;
CPL := 0;
```

1. If the NMI was being injected by VM entry, the existing treatment applies: physical-NMI blocking is not changed, but virtual NMIs are blocked if the "virtual NMIs" VM-execution control is 1.

A.2 Detailed Operation of ERETS

The appendix presents detailed pseudocode for the operation of ERETS:

```
IF IA32_EFER.LMA = 0 OR CS.L = 0 OR CR4.FRED = 0 OR CPL > 0
    THEN #UD;
FI;
// pop old context from regular stack and check it
pop8B newRIP;
pop8B tempCS;                   // not used to load CS
pop8B newRFLAGS;
pop8B newRSP;
pop8B tempSS;                   // not used to load SS
IF newRIP is not canonical relative to the current paging mode OR
    tempCS & FFFFFFFF_ECFCFFFFH ≠ current CS selector OR
    newRFLAGS & FFFFFFFF_FFC2802AH ≠ 2 OR   // enforce bit 1 set; VM, reserved bits clear
    tempSS & FFFFFFFFH ≠ current SS selector    // do not check bits 63:32
        THEN #GP(0);
FI;
NMI_unblock := tempCS[28];
pend_DB := tempCS[25];
STI_block:= tempCS[24];
// ERETS will not numerically increase stack level
newCSL := min{CSL,tempCS[17:16]};
// If supervisor shadow stacks are enabled, pop and check values from the shadow stack
IF CR4.CET = 1 AND IA32_S_CET.SH_STK_EN = 1
    THEN
        IF SSP & 7 ≠ 0                          // require 8-byte alignment
            THEN #CP(FAR-RET/IRET);
        FI;
        popSS_8B newSSP;
        popSS_8B checkSSLIP;
        popSS_8B checkSSSL;
        IF checkSSSL ≠ newCSL                   // 64-bit compare
            OR checkSSLIP ≠ newRIP
            OR newSSP & 3H ≠ 0
            THEN #CP(FAR-RET/IRET);
        FI;
        IF newSSP not canonical relative to current paging mode
            THEN #GP(0);
        FI;
        // If the stack level is changing, compare SSP to the FRED SSP MSR for the old stack level
        IF newCSL < CSL AND IA32_FRED_SSPi ≠ SSP    // i = CSL
            THEN #CP(FAR-RET/IRET);
        FI;
FI;

// update registers for return context
RIP := newRIP;
RFLAGS := newRFLAGS;                            // ERETS can set RFLAGS.RF to 1
RSP := newRSP;
```

```
CSL := newCSL;                                      // reflect in IA32_FRED_CONFIG[1:0]
IF CR4.CET = 1 AND IA32_S_CET.SH_STK_EN = 1
    THEN SSP := newSSP;
FI;
// update event-related state
IF NMI_unblock = 1
    THEN unblock NMIs;[1]
FI;
IF pend_DB = 1 AND RFLAGS.TF =1
    THEN pend a single-step debug exception (#DB) to be delivered after ERETS;[2]
FI;
IF STI_unblock = 1
    THEN establish STI blocking;
FI;
```

1. If in VMX non-root operation with the 1-setting of the “virtual NMIs” VM-execution control, this step unblocks **virtual** NMIs. See Section 9.
2. If ERETS began execution with RFLAGS.TF = 1, there will always be a single-step debug exception pending after ERETS, regardless of the values on the stack for RFLAGS.TF and CS.

A.3 Detailed Operation of ERETU

The appendix presents detailed pseudocode for the operation of ERETU:

```
IF IA32_EFER.LMA = 0 OR CS.L = 0 CR4.FRED = 0 OR CPL > 0
    THEN #UD;
FI;
IF CSL > 0
    THEN #GP(0);
FI;
// pop old context from regular stack and check it
pop8B newRIP;
pop8B tempCS;
pop8B newRFLAGS;
pop8B newRSP;
pop8B tempSS;
IF newCS & FFFFFFFF_EDFF0003H ≠ 3 OR             // enforce return to ring 3
    newRFLAGS & FFFFFFFF_FFC2B02AH ≠ 2 OR        // enforce bit 1 set; IOPL, VM, reserved bits clear
    newSS & FFFF0003H ≠ 3                        // do not check bits 63:32
        THEN #GP(0);
FI;
NMI_unblock := tempCS[28];
pend_DB := tempCS[25];
IF tempCS[15:0] = IA32_STAR[63:48] + 16 AND tempSS[15:0] = IA32_STAR[63:48] + 8
    THEN                                     // Return to ring 3 in standard 64-bit configuration
        // set newCS to standard values used ring 3 in 64-bit mode
            newCS.selector := (IA32_STAR[63:48] + 16) | 3;
            newCS.base := 0;
            newCS.limit := FFFFFH;
            newCS.type := 11;
            newCS.S := 1;
            newCS.DPL := 3;
            newCS.P := 1;
            newCS.L := 1;
            newCS.D := 0;
            newCS.G := 1;
        // set newSS to standard values for ring 3
            newSS.selector := (IA32_STAR[63:48] + 8) | 3;
            newSS.base := 0;
            newSS.limit := FFFFFH;
            newSS.type := 3;
            newSS.S := 1;
            newSS.DPL := 3;
            newSS.P := 1;
            newSS.B := 1;
            newSS.G := 1;
ELSIF tempCS[15:0] = IA32_STAR[63:48] AND tempSS[15:0] = IA32_STAR[63:48] + 8
    THEN
        // set newCS to standard values used ring 3 in compatibility mode
            newCS.selector := IA32_STAR[63:48] | 3;
            newCS.base := 0;
```

```
                newCS.limit := FFFFFH;
                newCS.type := 11;
                newCS.S := 1;
                newCS.DPL := 3;
                newCS.P := 1;
                newCS.L := 0;

                newCS.G := 1;
            // set newSS to standard values for ring 3
                newSS.selector := (IA32_STAR[63:48] + 8) | 3;
                newSS.base := 0;
                newSS.limit := FFFFFH;
                newSS.type := 3;
                newSS.S := 1;
                newSS.DPL := 3;
                newSS.P := 1;
                newSS.B := 1;
                newSS.G := 1;
        ELSE
            load newCS using tempCS[15:0];          // load each as is done by IRET, including
            load newSS using tempSS[15:0];          // checks that may lead to a fault
            IF newCS.L = 0 AND newRIP is not within newCS's limit
                THEN #GP(0);
            FI;
FI;
IF newCS.L = 1 AND newRIP is not canonical relative to current paging mode
    THEN #GP(0);
FI;
// If user shadow stacks are enabled, check new SSP value
IF CR4.CET = 1 AND IA32_U_CET.SH_STK_EN = 1 AND
    (newCS.L = 0 AND IA32_PL3_SSP[63:32] ≠ 0)// return to compatibility mode
    OR (newCS.L = 1 AND IA32_PL3_SSP not canonical relative to paging mode)
        THEN #GP(0);
FI;
// If supervisor shadow stacks are enabled, compare SSP to the FRED SSP MSR for stack level 0
IF CR4.CET = 1 AND IA32_S_CET.SH_STK_EN = 1 AND IA32_FRED_SSP0 ≠ SSP
    THEN #CP(FAR-RET/IRET);
FI;

// update registers for return context
RIP := newRIP;
RFLAGS := newRFLAGS;                        // ERETU can set RFLAGS.RF to 1
RSP := newRSP;                              // load all 64 bits regardless of new mode
CS := newCS;                                // selector and descriptor
SS := newSS;                                // selector and descriptor
CPL := 3;
// swap GS.base and IA32_KERNEL_GS_BASE
tempGSB := GS.base;
GS.base := IA32_KERNEL_GS_BASE;
IA32_KERNEL_GS_BASE := tempGSB;
```

```
IF CR4.CET = 1 AND IA32_U_CET.SH_STK_EN = 1
    THEN SSP := IA32_PL3_SSP;
FI;

// update event-related state
IF NMI_unblock = 1
    THEN unblock NMIs;[1]
FI;
IF pend_DB = 1 AND RFLAGS.TF =1
    THEN pend a single-step debug exception (#DB) to be delivered after ERETU;[2]
FI;
```

1. If in VMX non-root operation with the 1-setting of the “virtual NMIs” VM-execution control, this step unblocks **virtual** NMIs. See Section 9.
2. If ERETU began execution with RFLAGS.TF = 1, there will always be a single-step debug exception pending after ERETU, regardless of the values on the stack for RFLAGS.TF and CS.

B Event Stack Levels

Section 5.1.2 explains that FRED event delivery determines the new stack level. This determination is based on the CPL, the CSL, the event type, the event vector, and whether the event was encountered during FRED event delivery.

The principal determination is based on CPL. Delivery of events occurring when CPL = 3 always establish stack level 0 unless an exception has been encountered during FRED event delivery.[1] In the latter case, delivery of the nested exception (or the double fault, if one was generated) determines the new stack level as is done for events occurring when CPL = 0 and is explained in the following paragraphs.

The remainder of this appendix explains the determination of the new stack level for events that occur when CPL = 0 or when there has been a nested exception. It also provides details of the event type and vector reported for all cases (e.g., even for CPL = 3).

For these remaining situations, FRED event delivery establishes the new stack level as the maximum of the CSL and **event stack level**. The event stack level is determined as follows:

- If the event is an execution of INT *n* (opcode CD *n* for 8-bit value *n*), the event stack level is 0. The event type is 4 (software interrupt) and the vector is *n*.
- If the event is an execution of SYSCALL (opcode 0F 05),or SYSENTER (opcode 0F 34), the event stack level is 0. The event type is 7 (other event) and the vector is either 1 (SYSCALL) or 2 (SYSENTER).
- If the event is an execution of INT1 (opcode F1), INT3 (opcode CC), or INTO (opcode CE), the event stack level is selected using the IA32_FRED_STKLVLS MSR:
  - For INT1, the event stack level is IA32_FRED_STKLVLS[3:2]. The event type is 5 (privileged software exception) and the vector is 1.
  - For INT3, the event stack level is IA32_FRED_STKLVLS[7:6]. The event type is 6 (software exception) and the vector is 3.
  - For INTO, the event stack level is IA32_FRED_STKLVLS[9:8]. The event type is 6 (software exception) and the vector is 4.

Note: Execution of INTO results in FRED event delivery (of exception #OF) only if RFLAGS.OF = 1. Note also that INTO cannot be executed in ring 0 when FRED transitions are enabled because INTO is not valid in 64-bit mode and enabling FRED transitions prevents entry to compatibility mode in ring 0.

- If the event is a non-maskable interrupt (NMI), the event stack level is IA32_FRED_STKLVLS[5:4]. The event type is 2 (non-maskable interrupt) and the vector is 2.
- If the event is a maskable interrupt, the event stack level is IA32_FRED_CONFIG[10:9]. The event type is 0 (external interrupt) and the vector is that of the interrupt.
- If the event is an exception with vector *n* (other than those generated by INT1, INT3, or INTO), the event stack level is IA32_FRED_STKLVLS[2*n*+1,2*n*]. The event type is 3 (hardware exception) and the vector is *n*.

1. The following faults may be encountered during FRED event delivery: #GP, #PF, #SS, or #VE. Occurrence of any of these faults may generate a #DF. In addition, FRED event delivery may encounter #MC.
